Intravenous fat can also be provided to patients receiving central vein nutritional support. In this instance, dextrose concentrations should be decreased to provide a fixed concentration of energy. Intravenous fat has been shown to be equivalent to intravenous dextrose in providing energy to spare protein. Intravenous fat is associated with less glucose intolerance, less production of carbon dioxide, and less fatty infiltration of the liver and has been increasingly utilized in patients with hyperglycemia, respiratory failure, and liver disease. Intravenous fat has also been increasingly used in patients with large estimated energy requirements. The maximum glucose utilization rate is approximately 5–7 mg/min/kg. Patients who require additional calories can be given them as fat to prevent excess administration of dextrose. Intravenous fat can also be used to prevent essential fatty acid deficiency. The optimal ratio of carbohydrate and fat in parenteral nutritional support has not been determined.

Infusion of parenteral solutions should be started slowly to prevent hyperglycemia and other metabolic complications. Typical solutions are given initially at a rate of 50 mL/h and advanced by about the same amount every 24 hours until the desired final rate is reached.

### Complications of Parenteral Nutritional Support

Complications of central vein nutritional support occur in up to 50% of patients. Although most are minor and easily managed, significant complications will develop in about 5% of patients. Complications of central vein nutritional support can be divided into catheter-related complications and metabolic complications.

Catheter-related complications can occur during insertion or while the catheter is in place. Pneumothorax, hemothorax, arterial laceration, air emboli, and brachial plexus injury can occur during catheter placement. The incidence of these complications is inversely related to the experience of the physician performing the procedure but will occur in at least 1–2% of cases even in major medical centers. Each catheter placement should be documented by chest radiograph prior to initiation of nutritional support.

Catheter thrombosis and catheter-related sepsis are the most important complications of indwelling catheters. Patients with indwelling central vein catheters in whom fever develops without an apparent source should have their lines changed over a wire or removed immediately, the tip quantitatively cultured, and antibiotics begun empirically. Quantitative tip cultures and blood cultures will help guide further antibiotic therapy. Catheter-related sepsis occurs in 2–3% of patients even if maximal efforts are made to prevent infection.

Metabolic complications of central vein nutritional support occur in over 50% of patients (Table 29–3). Most

Table 29-3. Metabolic complications of parenteral nutritional support.
are minor and easily managed, and termination of support is seldom necessary.

**PATIENT MONITORING DURING NUTRITIONAL SUPPORT**

Every patient receiving enteral or parenteral nutritional support should be monitored closely. Formal nutritional support teams composed of a physician, a nurse, a dietitian, and a pharmacist have been shown to decrease the rate of complications.

Patients should be monitored both for the adequacy of treatment and to prevent complications or detect them early when they occur. Because estimates of nutritional requirements are imprecise, frequent reassessment is necessary. Daily intakes should be recorded and compared with estimated requirements. Body weight, hydration status, and overall clinical status should be followed. Patients who do not appear to be responding as anticipated can be evaluated for nitrogen balance by means of the following equation:

\[
\text{Nitrogen balance} = \frac{24\text{-hour protein intake (g)}}{6.25} - \left( \frac{24\text{-hour urinary nitrogen (g)}}{4} + 4 \right)
\]

Patients with positive nitrogen balances can be continued on their current regimens; patients with negative balances should receive moderate increases in calorie and protein intake and then be reassessed. Monitoring for metabolic complications includes daily measurements of electrolytes; serum glucose, phosphorus, magnesium, calcium, and creatinine; and BUN until the patient is stabilized. Once the patient is stabilized, electrolytes, phosphorus, calcium, magnesium, and glucose should be obtained at least twice weekly. Red blood cell folate, zinc, and copper should be checked at least once a month.
FEVER OF UNKNOWN ORIGIN (FUO)

**Essentials of Diagnosis**
- Illness of at least 3 weeks duration.
- Fever over 38.3°C on several occasions.
- Diagnosis has not been made after three outpatient visits or 3 days of hospitalization.

**General Considerations**

The intervals specified in the criteria for the diagnosis of FUO are arbitrary ones intended to exclude patients with protracted but self-limited viral illnesses and to allow time for the usual radiographic, serologic, and cultural studies to be performed. Because of costs of hospitalization and the availability of most screening tests on an outpatient basis, the original criterion requiring 1 week of hospitalization has been modified to accept patients in whom a diagnosis has not been made after three outpatient visits or 3 days of hospitalization.

Several additional categories of FUO have been added: (1) Hospital-associated FUO refers to the hospitalized patient with fever of 38.3°C or higher on several occasions, due to a process not present or incubating at the time of admission, in whom initial cultures are negative and the diagnosis remains unknown after 3 days of investigation (see Health care-associated Infections below). (2) Neutropenic FUO includes patients with fever of 38.3°C or higher on several occasions with < 500 neutrophils per microliter in whom initial cultures are negative and the diagnosis remains uncertain after 3 days (see Chapter 2 and Infections in the Immunocompromised Patient, below). (3) HIV-associated FUO pertains to HIV-positive patients with fever of 38.3°C or higher who have been febrile for 4 weeks or more as an outpatient or 3 days as an inpatient, in whom the diagnosis remains uncertain after 3 days of investigation with at least 2 days for cultures to incubate (see Chapter 31). Although not usually considered separately, FUO in solid organ transplant recipients is a common scenario with a unique differential diagnosis and is discussed below.

For a general discussion of fever, see the section on fever and hyperthermia in Chapter 2.

**A. Common Causes**

Most cases represent unusual manifestations of common diseases and not rare or exotic diseases—eg, tuberculosis, endocarditis, gallbladder disease, and HIV (primary infection or opportunistic infection) are more common causes of FUO than Whipple disease or familial Mediterranean fever.

**B. Age of Patient**

In adults, infections (25–40% of cases) and cancer (25–40% of cases) account for the majority of FUOs. In children, infections are the most common cause of FUO (30–50% of cases) and cancer a rare cause (5–10% of cases). Autoimmune disorders occur with equal frequency in adults and children (10–20% of cases), but the diseases differ. Juvenile rheumatoid arthritis is particularly common in children, whereas systemic lupus erythematosus, granulomatosis with polyangiitis (formerly Wegener granulomatosis), and polyarteritis nodosa are more common in adults. Still disease, giant cell arteritis, and polymyalgia rheumatica occur exclusively in adults. In the elderly (over 65 years of age), multisystem immune-mediated diseases such as temporal arteritis, polymyalgia rheumatica, sarcoidosis, rheumatoid arthritis, and granulomatosis with polyangiitis (formerly Wegener granulomatosis) account for 25–30% of all FUOs.

**C. Duration of Fever**

The cause of FUO changes dramatically in patients who have been febrile for 6 months or longer. Infection, cancer, and autoimmune disorders combined account for only 20% of FUOs in these patients. Instead, other entities such as granulomatous diseases (granulomatous hepatitis, Crohn disease, ulcerative colitis) and factitious fever become important causes. One-fourth of patients who say they have been febrile for 6 months or longer actually have...
no true fever or underlying disease. Instead, the usual normal circadian variation in temperature (temperature 0.5–1°C higher in the afternoon than in the morning) is interpreted as abnormal. Patients with episodic or recurrent fever (ie, those who meet the criteria for FUO but have fever-free periods of 2 weeks or longer) are similar to those with prolonged fever. Infection, malignancy, and autoimmune disorders account for only 20–25% of such fevers, whereas various miscellaneous diseases (Crohn disease, familial Mediterranean fever, allergic alveolitis) account for another 25%. Approximately 50% of cases remain undiagnosed but have a benign course with eventual resolution of symptoms.

D. Immunologic Status

In the neutropenic patient, fungal infections and occult bacterial infection are important causes of FUO. In the patient taking immunosuppressive medications (particularly organ transplant patients), cytomegalovirus (CMV) infections are a frequent cause of fever, as are fungal infections, nocardiosis, *Pneumocystis jiroveci* (formerly *P carinii*) pneumonia, and mycobacterial infections.

E. Classification of Causes of FUO

Most patients with FUO will fit into one of five categories.

1. **Infection**—Both systemic and localized infections can cause FUO. Tuberculosis and endocarditis are the most common systemic infections, but mycoses, viral diseases (particularly infection with Epstein-Barr virus and CMV), toxoplasmosis, brucellosis, Q fever, cat-scratch disease, salmonellosis, malaria, and many other less common infections have been implicated. Primary infection with HIV or opportunistic infections associated with AIDS—particularly mycobacterial infections—can also present as FUO. The most common form of localized infection causing FUO is an occult abscess. Liver, spleen, kidney, brain, and bone abscesses may be difficult to detect. A collection of pus may form in the peritoneal cavity or in the subdiaphragmatic, subhepatic, paracolic, or other areas. Cholangitis, osteomyelitis, urinary tract infection, dental abscess, or paranasal sinusitis may cause prolonged fever.

2. **Neoplasms**—Many cancers can present as FUO. The most common are lymphoma (both Hodgkin and non-Hodgkin) and leukemia. Posttransplant lymphoproliferative disorders may also present with fever. Other diseases of lymph nodes, such as angioimmunoblastic lymphoma and Castleman disease, can also cause FUO. Primary and metastatic tumors of the liver are frequently associated with fever, as are renal cell carcinomas. Atrial myxoma is an often forgotten neoplasm that can result in fever. Chronic lymphocytic leukemia and multiple myeloma are rarely associated with fever, and the presence of fever in patients with these diseases should prompt a search for infection.

3. **Autoimmune disorders**—Still disease, systemic lupus erythematosus, cryoglobulinemia, and polyarteritis nodosa are the most common causes of autoimmune-associated FUO. Giant cell arteritis and polymyalgia rheumatica are seen almost exclusively in patients over 50 years of age and are nearly always associated with an elevated erythrocyte sedimentation rate (>40 mm/h).

4. **Miscellaneous causes**—Many other conditions have been associated with FUO but less commonly than the foregoing types of illness. Examples include thyroiditis, sarcoidosis, Whipple disease, familial Mediterranean fever, recurrent pulmonary emboli, alcoholic hepatitis, drug fever, and factitious fever.

5. **Undiagnosed FUO**—Despite extensive evaluation, the diagnosis remains elusive in 15% or more of patients. Of these patients, the fever abates spontaneously in about 75% with no diagnosis; in the remainder, more classic manifestations of the underlying disease appear over time.

▶ **Clinical Findings**

Because the evaluation of a patient with FUO is costly and time-consuming, it is imperative to first document the presence of fever. This is done by observing the patient while the temperature is being taken to ascertain that fever is not factitious (self-induced). Associated findings that accompany fever include tachycardia, chills, and piloerection. A thorough history—including family, occupational, social (sexual practices, use of injection drugs), dietary (unpasteurized products, raw meat), exposures (animals, chemicals), and travel—may give clues to the diagnosis. Repeated physical examination may reveal subtle, evanescent clinical findings essential to diagnosis.

A. **Laboratory Tests**

In addition to routine laboratory studies, blood cultures should always be obtained, preferably when the patient has not taken antibiotics for several days, and should be held by the laboratory for 2 weeks to detect slow-growing organisms. Cultures on special media are requested if *Legionella, Bartonella*, or nutritionally deficient streptococci are possible pathogens. “Screening tests” with immunologic or microbiologic serologies (“febrile agglutinins”) are of low yield and should not be done. If the history or physical examination suggests a specific diagnosis, specific serologic tests with an associated fourfold rise or fall in titer may be useful. Because infection is the most common cause of FUO, other body fluids are usually cultured, ie, urine, sputum, stool, cerebrospinal fluid, and morning gastric aspirates (if one suspects tuberculosis). Direct examination of blood smears may establish a diagnosis of malaria or relapsing fever (*Borrelia*).

B. **Imaging**

All patients with FUO should have a chest radiograph. Studies such as sinus films, upper gastrointestinal series with small bowel follow-through, barium enema, proctosigmoidoscopy, and evaluation of gallbladder function are reserved for patients who have symptoms, signs, or a history that suggest disease in these body regions. CT scan of the abdomen and pelvis is also frequently performed and is particularly useful for looking at the liver, spleen, and retroperitoneum. When the CT scan is abnormal, the findings often lead to a specific diagnosis. A normal CT scan is not
quite as useful; more invasive procedures such as biopsy or exploratory laparotomy may be needed. The role of MRI in the investigation of FUO has not been evaluated. In general, however, MRI is better than CT for detecting lesions of the nervous system and is useful in diagnosing various vasculitides. Ultrasound is sensitive for detecting lesions of the kidney, pancreas, and biliary tree. Echocardiography should be used if one is considering endocarditis or atrial myxoma. Transesophageal echocardiography is more sensitive than surface echocardiography for detecting valvular lesions, but even a negative transesophageal study does not exclude endocarditis (10% false-negative rate). The usefulness of radionuclide studies in diagnosing FUO is variable. Some experts use positron emission tomography (PET) in conjunction with CT scans early in the investigation of FUO. However, more studies are needed before this practice can be more fully integrated into clinical practice. Theoretically, a gallium or PET scan would be more helpful than an indium-labeled white blood cell scan because gallium and fluorodeoxyglucose may be useful for detecting infection, inflammation, and neoplasm whereas the indium scan is useful only for detecting infection. Indium-labeled immunoglobulin may prove to be useful in detecting infection and neoplasm and can be used in the neutropenic patient. It is not sensitive for lesions of the liver, kidney, and heart because of high background activity. In general, radionuclide scans are plagued by high rates of false-positive and false-negative results that are not useful when used as screening tests and, if done at all, are limited to those patients whose history or examination suggests local inflammation or infection.

C. Biopsy

Invasive procedures are often required for diagnosis. Any abnormal finding should be aggressively evaluated: Headache calls for lumbar puncture to rule out meningitis; skin rash should be biopsied for cutaneous manifestations of collagen vascular disease or infection; and enlarged lymph nodes should be aspirated or biopsied for neoplasm and sent for culture. Bone marrow aspiration with biopsy is a relatively low-yield procedure (15–25%; except in HIV-positive patients, in whom mycobacterial infection is a common cause of FUO), but the risk is low and the procedure should be done if other less invasive tests have not yielded a diagnosis, particularly in persons with hematologic abnormalities. Liver biopsy will yield a specific diagnosis in 10–15% of patients with FUO and should be considered in any patient with abnormal liver function tests even if the liver is normal in size. CT scanning and MRI have decreased the need for exploratory laparotomy; however, surgical visualization and biopsies should be considered when there is continued deterioration or lack of diagnosis.

Treatment

An empiric course of antimicrobials for possible cystitis (eg, ciprofloxacin, 500 mg orally twice daily for 3 days) should be considered if an infectious diagnosis is strongly suspected. However, if there is no clinical response, it is imperative to stop therapy and reevaluate. Once definitive culture results return, streamlining therapy to the most narrow-spectrum antimicrobial should take place. Empiric administration of corticosteroids should be discouraged because they can suppress fever and exacerbate many infections.

When to Refer

- Any patient with FUO and progressive weight loss and other constitutional signs.
- Any immunocompromised patient (eg, transplant recipients and HIV-infected patients).
- Infectious diseases specialists may also be able to coordinate and interpret specialized testing (eg, Q fever serologies) with outside agencies, such as the US Centers for Disease Control and Prevention.

When to Admit

- Any patient who is rapidly declining with weight loss where hospital admission may expedite work-up.
- If FUO is present in immunocompromised patients, such as those who are neutropenic from recent chemotherapy or those who have undergone transplantation (particularly in the previous 6 months).

Immunocompromised patients have defects in their natural defense mechanisms resulting in an increased risk for infection. In addition, infection is often severe, rapidly progressive, and life threatening. Organisms that are not usually problematic in the immunocompetent person may be important pathogens in the compromised patient (eg, *Staphylococcus epidermidis*, *Corynebacterium jeikeium*, *Propionibacterium acne*, *Bacillus* species). Therefore, culture results must be interpreted with caution, and isolates should not be disregarded as merely contaminants. Although the type of immunodeficiency is associated with specific infectious disease syndromes, any pathogen can cause infection in any immunosuppressed patient at any time. Thus, a systematic evaluation is required to identify a specific organism.

### A. Impaired Humoral Immunity

Defects in humoral immunity are often congenital, although hypogammaglobulinemia can occur in multiple myeloma, chronic lymphocytic leukemia, and in patients who have undergone splenectomy. Patients with ineffective humoral immunity lack opsonizing antibodies and are at particular risk for infection with encapsulated organisms, such as *Haemophilus influenzae*, *Neisseria meningitidis* and *Streptococcus pneumoniae*.

### B. Granulocytopenia (Neutropenia)

Granulocytopenia is common following hematopoietic cell transplantation (“stem cell transplantation”) and among patients with solid tumors—as a result of myelosuppressive chemotherapy—and in acute leukemias. The risk of infection begins to increase when the absolute granulocyte count falls below 1000/mcL, with a dramatic increase in frequency and severity when the granulocyte count falls below 100/mcL. The infection risk is also increased with a rapid rate of decline of neutrophils and with a prolonged period of neutropenia. The granulocytopenic patient is particularly susceptible to infections with gram-negative enteric organisms, *Pseudomonas*, gram-positive coccic (particularly *Staphylococcus aureus*, *S epidermidis*, and viridans streptococci), *Candida*, *Aspergillus*, and other fungi that have recently emerged as pathogens such as *Trichosporon*, *Scedosporium*, *Fusarium*, and the mucormycoses.

### C. Impaired Cellular Immunity

Patients with cellular immune deficiency encompass a large and heterogeneous group, including patients with HIV infection (see Chapter 31); patients with lymphoreticular malignancies, such as Hodgkin disease; and patients receiving immunosuppressive medications, such as corticosteroids, cyclosporine, tacrolimus, and other cytotoxic drugs. This latter group—those who are immunosuppressed as a result of medications—includes patients who have undergone solid organ transplantation, many patients receiving therapy for solid tumors, and patients receiving prolonged high-dose corticosteroid treatment (eg, for asthma, temporal arteritis, systemic lupus). Patients taking tumor necrosis factor (TNF) inhibitors, such as etanercept and infliximab, are also included in this category. Patients with cellular immune dysfunction are susceptible to infections by a large number of organisms, particularly ones that replicate intracellularly. Examples include bacteria, such as *Listeria*, *Legionella*, *Salmonella*, and *Mycobacterium*; viruses, such as herpes simplex, varicella, and CMV; fungi, such as *Cryptococcus*, *Coccidioides*, *Histoplasma*, and *Pneumocystis*; and protozoa, such as *Toxoplasma*. Patients taking TNF inhibitors have specific defects that increase risk of bacterial, mycobacterial (particularly tuberculosis), and fungal infections (primary and reactivation).

### D. Hematopoietic Cell Transplant Recipients

The length of time it takes for complications to occur in hematopoietic cell transplant recipients can be helpful in determining the etiologic agent. In the early (preengraftment) posttransplant period (day 1–21), patients will become severely neutropenic for 7–21 days. Patients are at risk for gram-positive (particularly catheter-related) and gram-negative bacterial infections, as well as herpes simplex virus, respiratory syncytial virus, and fungal infections. In contrast to solid organ transplant recipients, the source of fever is unknown in 60–70% of hematopoietic cell transplant patients. Between 3 weeks and 3 months posttransplant, infections with CMV, adenovirus, *Aspergillus*, and *Candida* are most common. *P. jiroveci* pneumonia is possible, particularly in patients who receive additional immunosuppression for treatment of graft-versus-host disease. Patients continue to be at risk for infectious complications beyond 3 months following transplantation, particularly those who have received allogeneic transplantation and those who are taking immunosuppressive therapy for chronic graft-versus-host disease. *Varicella-zoster* is common, and *Aspergillus* and CMV infections are increasingly seen in this period as well.

### E. Solid Organ Transplant Recipients

The length of time it takes for infection to occur following solid organ transplantation can also be helpful in determining the infectious origin. Immediate postoperative infections often involve the transplanted organ. Following lung transplantation, pneumonia and mediastinitis are particularly common; following liver transplantation, intra-abdominal abscess, cholangitis, and peritonitis may be seen; after kidney transplantation, urinary tract infections, perinephric abscesses, and infected lymphoceles can occur.

Most infections that occur in the first 2–4 weeks posttransplant are related to the operative procedure and to hospitalization itself (wound infection, intravenous catheter infection, urinary tract infection from a Foley catheter) or are related to the transplanted organ. In rare instances, donor derived infections (eg, West Nile virus, tuberculosis) may present during this time period. Infections that occur between the first and sixth months are often related to immunosuppression. During this period, reactivation of viruses, such as herpes simplex, varicella-zoster, and CMV is quite common. Opportunistic infections with fungi...
(eg, Candida, Aspergillus, Cryptococcus, Pneumocystis), Listeria monocytogenes, Nocardia, and Toxoplasma are also common. After 6 months, if immunosuppression has been reduced to maintenance levels, infections that would be common. After 6 months, if immunosuppression has been reduced to maintenance levels, infections that would be expected in any population occur. Patients with poorly functioning allografts receiving long-term immunosuppression therapy continue to be at risk for opportunistic infections.

**F. Other Immunocompromised States**

A large group of patients who are not specifically immunodeficient are at increased risk for infection due to debilitating injury (eg, burns or severe trauma), invasive procedures (eg, chronic central intravenous catheters, Foley catheters, dialysis catheters), central nervous system dysfunction (which predisposes patients to aspiration pneumonia and decubitus ulcers), obstructing lesions (eg, pneumonia due to an obstructed bronchus, pyelonephritis due to nephrolithiasis, cholangitis secondary to cholelithiasis), and use of broad-spectrum antibiotics. Patients with diabetes mellitus have alterations in cellular immunity, resulting in mucormycosis, emphysematous pyelonephritis, and foot infections.

**Clinical Findings**

**A. Laboratory Findings**

Routine evaluation includes complete blood count with differential, chest radiograph, and blood cultures; urine and respiratory cultures should be obtained if indicated clinically or radiographically. Any focal complaints (localized pain, headache, rash) should prompt imaging and cultures appropriate to the site.

Patients who remain febrile without an obvious source should be evaluated for viral infection (serum CMV antigen test or polymerase chain reaction), abscesses (which usually occur near previous operative sites), candidiasis involving the liver or spleen, or aspergillosis. Serologic evaluation may be helpful if toxoplasmosis or an endemic fungal infection (coccidioidomycosis, histoplasmosis) is a possible cause. Antigen based assays may be useful for the diagnosis of aspergillosis (detected by galactomannan level in serum or bronchoalveolar lavage fluid), or other invasive fungal disease, including Pneumocystis infection (serum (1→β-1-glucan level).

**B. Special Diagnostic Procedures**

Special diagnostic procedures should also be considered. The cause of pulmonary infiltrates can be easily determined with simple techniques in some situations—eg, induced sputum yields a diagnosis of Pneumocystis pneumonia in 50–80% of AIDS patients with this infection. In other situations, more invasive procedures may be required (bronchoalveolar lavage, transbronchial biopsy, open lung biopsy). Skin, liver, or bone marrow biopsy may be helpful in establishing a diagnosis.

**Differential Diagnosis**

Transplant rejection, organ ischemia and necrosis, thrombophlebitis, and lymphoma (posttransplant lymphoproliferative disease) may all present as fever and must be considered in the differential diagnosis.

**Prevention**

There is great interest in preventing infection with prophylactic antimicrobial regimens but no uniformity of opinion about optimal drugs or dosage regimens. Hand washing is the simplest and most effective means of decreasing hospital-associated infections, especially in the compromised patient. Invasive devices such as central and peripheral lines and Foley catheters are potential sources of infection. Some centers use laminar airflow isolation or high-efficiency particulate air (HEPA) filtering in hematopoietic cell transplant patients. Rates of infection and episodes of febrile neutropenia, but not mortality, are decreased if colony-stimulating factors are used during chemotherapy or during stem-cell transplantation.

**A. Pneumocystis & Herpes Simplex Infections**

Trimethoprim-sulfamethoxazole (TMP-SMZ), one double-strength tablet orally three times a week, one double-strength tablet twice daily on weekends, or one single-strength tablet daily for 3–6 months, is frequently used to prevent Pneumocystis infections in transplant patients. In patients allergic to TMP-SMZ, dapsone, 50 mg daily or 100 mg three times weekly, is recommended. Glucose-6-phosphate dehydrogenase (G6PD) levels should be determined before therapy when the latter is instituted. Acyclovir prevents herpes simplex infections in bone marrow and solid organ transplant recipients and is given to seropositive patients who are not receiving acyclovir or ganciclovir for CMV prophylaxis. The usual dose is 200 mg orally three times daily for 4 weeks (hematopoietic cell transplants) to 12 weeks (other solid organ transplants).

**B. CMV**

No uniformly accepted approach has been adopted for prevention of CMV. Prevention strategies often depend on the serologic status of the donor and recipient and the organ transplanted, which determines the level of immunosuppression after transplant. In solid organ transplants (liver, kidney, heart, lung), the greatest risk of developing CMV disease is in seronegative patients who receive organs from seropositive donors. These high-risk patients usually receive oral ganciclovir, 900 mg daily for 3–6 months (longer in lung transplant recipients). Other solid organ transplant recipients (seropositive recipients) are at lower risk for developing CMV disease but still usually receive oral ganciclovir for 3 months. The lowest risk group for the development of CMV disease is in seronegative patients who receive organs from seronegative donors. Typically, no CMV prophylaxis is used in this group. Ganciclovir and valganciclovir also prevent herpes virus reactivation. Because immunosuppression is increased during periods of rejection, patients treated for rejection usually receive CMV prophylaxis during rejection therapy.

Recipient of hematopoietic cell transplants are more severely immunosuppressed than recipients of solid organ transplants, are at greater risk for developing serious CMV infection (usually CMV reactivation), and thus usually receive more aggressive prophylaxis. Two approaches have been used: universal prophylaxis or preemptive therapy.
In the former, all high-risk patients (seropositive patients who receive allogeneic transplants) may receive oral valganciclovir, 900 mg daily to day 100. This method is costly and associated with significant bone marrow toxicity. Alternatively, patients can be monitored without specific prophylaxis and have blood sampled weekly for the presence of CMV. If CMV is detected by an antigenemia assay or by polymerase chain reaction, preemptive therapy is instituted with oral valganciclovir, 900 mg twice daily for a minimum of 2–3 weeks followed by oral valganciclovir at 900 mg daily until day 100. This preemptive approach is effective but does miss a small number of patients in whom CMV disease would have been prevented had prophylaxis been used. Other preventive strategies include use of CMV-negative or leukocyte-depleted blood products for CMV-seronegative recipients.

C. Other Organisms

Routine decontamination of the gastrointestinal tract to prevent bacteremia in the neutropenic patient is not recommended. Prophylactic administration of antibiotics in the afebrile, asymptomatic neutropenic patient is controversial, although many centers have adopted this strategy. Rates of bacteremia are decreased, but overall mortality is not affected and emergence of resistant organisms is a risk. Use of intravenous immunoglobulin is reserved for the small number of patients with severe hypogammaglobulinemia following bone marrow transplantation and should not be routinely administered to all transplant patients.

Prophylaxis with antifungal agents to prevent invasive mold (primarily Aspergillus) and yeast (primarily Candida) infections is routinely used, but the optimal agent, dose, and duration have not been standardized. Lipid-based preparations of amphotericin B, aerosolized amphotericin B, intravenous and oral fluconazole or voriconazole, and oral posaconazole solution are all prophylactic options in the neutropenic patient. Because voriconazole is superior to amphotericin B for documented Aspergillus infections and because posaconazole prophylaxis (compared with fluconazole) has been shown to result in fewer cases of invasive aspergillosis among allogeneic stem cell transplant recipients with graft-versus-host disease, one approach to prophylaxis is to use oral fluconazole (400 mg/d) for patients at low risk for developing fungal infections (those who receive autologous bone marrow transplants) and oral voriconazole (200 mg twice daily) or oral posaconazole (200 mg solution three times daily) for those at high risk (allogeneic transplants, graft-versus-host disease) at least until engraftment (usually 30 days). In solid organ transplant recipients, the risk of invasive fungal infection varies considerably (1–2% in liver, pancreas, and kidney transplants and 6–8% in heart and lung transplants). Whether universal prophylaxis or observation with preemptive therapy is the best approach has not been determined. Although fluconazole is effective in preventing yeast infections, emergence of fluconazole-resistant Candida and molds (Fusarium, Aspergillus, Mucor) has raised concerns about its routine use as a prophylactic agent.

Given the high risk of reactivation of tuberculosis in patients taking TNF inhibitors, all patients should be screened for latent tuberculosis infection (LTBI) with a tuberculin skin test or an interferon-gamma release assay prior to the start of therapy. If LTBI is diagnosed, treatment with the TNF inhibitors should be delayed until treatment for LTBI is completed. There is also a marked risk of reactivation of hepatitis B and hepatitis C in patients taking TNF inhibitors; patients should also be screened for these viruses when TNF inhibitor treatment is being considered.

Treatment

A. General Measures

Because infections in the immunocompromised patient can be rapidly progressive and life-threatening, diagnostic procedures must be performed promptly, and empiric therapy is usually instituted. While reduction or discontinuation of immunosuppressive medication may jeopardize the viability of the transplanted organ, this measure may be necessary if the infection is life-threatening. Hematopoietic growth factors (granulocyte and granulocyte-macrophage colony-stimulating factors) stimulate proliferation of bone marrow stem cells, resulting in an increase in peripheral leukocytes. These agents shorten the period of neutropenia and have been associated with reduction in infection.

B. Specific Measures

Antimicrobial drug therapy ultimately should be tailored to culture results. While combinations of antimicrobials may be used to provide synergy or to prevent resistance, the primary reason for empiric combination therapy is broad-spectrum coverage of multiple pathogens (since infections in these patients are often polymicrobial).

Empiric therapy is often instituted at the earliest sign of infection in the immunosuppressed patient because prompt therapy favorably affects outcome. The antibiotic or combination of antibiotics used depends on the degree of immune compromise and the site of infection. For example, in the febrile neutropenic patient, an algorithmic approach to therapy is often used. Febrile neutropenic patients should be empirically treated with broad-spectrum agents active against gram-positive organisms, Pseudomonas aeruginosa, and other gram-negative bacilli (such as cefepime 2 g every 8 hours intravenously). The addition of vancomycin, 10–15 mg/kg/dose intravenously every 12 hours, should be considered in those patients with suspected infection due to methicillin-resistant Staphylococcus aureus (MRSA), S. epidermidis, and enterococcus. Continued neutropenic fever necessitates broadening of antibacterial coverage from cefepime to agents such as imipenem 500 mg every 6 hours or meropenem 1 g every 8 hours intravenously with or without tobramycin 5 mg/kg intravenously every 24 hours. Antifungal agents (such as voriconazole, 200 mg intravenously or orally every 12 hours, or caspofungin, 50 mg daily intravenously) should be added if fevers continue after 5–7 days of broad-spectrum antibacterial therapy. Regardless of whether the patient becomes afebrile, therapy is continued until resolution of neutropenia. Failure to continue antibiotics through the period of neutropenia has been associated with increased morbidity and mortality.
Patients with fever and low-risk neutropenia (neutropenia expected to persist for <10 days, no comorbid complications requiring hospitalization, and cancer adequately treated) can be treated with oral antibiotic regimens, such as ciprofloxacin, 750 mg every 12 hours, plus amoxicillin-clavulanic acid, 500 mg every 8 hours. Antibiotics are continued as long as the patient is neutropenic even if a source is not identified. In the organ transplant patient with interstitial infiltrates, the main concern is infection with Pneumocystis or Legionella species, so that empiric treatment with a macrolide (or fluoroquinolone) and TMP-SMZ, 15 mg/kg/d orally or intravenously (based on trimethoprim component) would be reasonable in those patients not receiving TMP-SMZ prophylaxis. If the patient does not respond to empiric treatment, a decision must be made to add more antimicrobial agents or perform invasive procedures (see above) to make a specific diagnosis. By making a definite diagnosis, therapy can be specific, thereby reducing selection pressure for resistance and superinfection.

**When to Refer**

- Any immunocompromised patient with an opportunistic infection.
- Patients with potential drug toxicities and drug interactions related to antimicrobials where alternative agents are sought.
- Patients with LTBI in whom therapy with TNF inhibitors is planned.

**When to Admit**

Immunocompromised patients who are febrile, or those without fevers in whom an infection is suspected, particularly in the following groups: solid-organ or hematopoietic stem cell transplant recipient (particularly in the first 6 months), neutropenic patients, patients receiving TNF inhibitors, transplant recipients who have had recent rejection episodes (including graft-versus-host disease).

---

**HEALTH CARE–ASSOCIATED INFECTIONS**

**ESSENTIALS OF DIAGNOSIS**

- Health care–associated infections are acquired during the course of receiving health care treatment for other conditions.
- Hospital-associated infections are a subset of health care–associated infections defined as those not present or incubating at the time of hospital admission and developing 48 hours or more after admission.
- Most health care–associated infections are preventable.
- Hand washing is the most effective means of preventing health care–associated infections and should be done routinely even when gloves are worn.

**General Considerations**

In the United States, approximately 5% of patients acquire a health care–associated infection, resulting in prolongation of the hospital stay, increase in cost of care, significant morbidity, and a 5% mortality rate. The most common infections are urinary tract infections, usually associated with Foley catheters or urologic procedures; bloodstream infections, most commonly from indwelling catheters but also from secondary sites, such as surgical wounds, abscesses, pneumonia, the genitourinary tract, and the gastrointestinal tract; pneumonia in intubated patients or those with altered levels of consciousness; surgical wound infections; MRSA infections; and *Clostridium difficile* colitis.

Some general principles are helpful in preventing, diagnosing, and treating health care–associated infections:

1. Many infections are a direct result of the use of invasive devices for monitoring or therapy, such as intravascular catheters, Foley catheters, shunts, surgical drains, catheters placed by interventional radiology for drainage, nasogastric tubes, and orotracheal or nasotracheal tubes for ventilatory support. Early removal of such devices reduces the possibility of infection.
2. Patients in whom health care–associated infections develop are often critically ill, have been hospitalized for extended periods, and have received several courses of antimicrobials.
of broad-spectrum antibiotic therapy. As a result, health care–associated infections are often due to multidrug resistant pathogens and are different from those encountered in community-acquired infections. For example, *S aureus* and *S epidermidis* (a frequent cause of prosthetic device infection) are often resistant to nafcillin and cephalosporins and require vancomycin for therapy; *Enterococcus faecium* resistant to ampicillin and vancomycin; gram-negative infections caused by *Pseudomonas*, *Citrobacter*, *Enterobacter*, *Acinetobacter*, and *Stenotrophomonas*, which may be resistant to most antibacterials. When choosing antibiotics to treat the seriously ill patient with a health care–associated infection, antimicrobial history and the “local ecology” must be considered. In the most seriously ill patients, broad-spectrum coverage with vancomycin and a carbapenem with or without an aminoglycoside is recommended. Once a pathogen is isolated and susceptibilities are known, the most narrow spectrum, least toxic, most cost-effective drug should be used.

Widespread use of antimicrobial drugs contributes to the selection of drug-resistant organisms, thus every effort should be made to limit the spectrum of coverage and unnecessary duration. All too often, unreliable or uninterpretable specimens are obtained for culture that result in unnecessary use of antibiotics. The best example of this principle is the diagnosis of line-related or bloodstream infection in the febrile patient (see below). To avoid unnecessary use of antibiotics, thoughtful consideration of culture results is mandatory. A positive wound culture without signs of inflammation or infection, a positive sputum culture without pulmonary infiltrates on chest radiograph, or a positive urine culture in a catheterized patient without symptoms or signs of pyelonephritis are all likely to represent colonization, not infection.

### Clinical Findings

#### A. Symptoms and Signs

Catheter-associated infections have a variable presentation, depending on the type of catheter used (peripheral or central venous catheters, nontunneled or tunneled). Local signs of infection may be present at the insertion site, with pain, erythema, and purulence. Fever is often absent in uncomplicated infections and if present, may indicate more disseminated disease such as bacteremia, cellulitis and septic thrombophlebitis. Often signs of infection at the insertion site are absent.

1. Fever in an intensive care unit patient—Fever complicates up to 70% of patients in intensive care units, and the etiology of the fever may be infectious or noninfectious. Common infectious causes include catheter-associated infections, hospital-acquired and ventilator-associated pneumonia (see Chapter 9), surgical site infections, urinary tract infections, and sepsis. Clinically relevant sinusitis is relatively uncommon in the patient in the intensive care unit.

   An important noninfectious cause is thromboembolic disease. Fever in conjunction with refractory hypotension and shock may suggest sepsis; however, adrenal insufficiency, thyroid storm, and transfusion reaction may have a similar clinical presentation. Drug fever is difficult to diagnose and is usually a diagnosis of exclusion unless there are other signs of hypersensitivity, such as a typical maculopapular rash.

2. Fever in the postoperative patient—Postoperative fever is very common and in many cases resolves spontaneously. Etiologies are both infectious and noninfectious. Timing of the fever in relation to the surgery and the nature of the surgical procedure may help diagnostically.

   A. **Immediate fever (in the first few hours after surgery)**—Immediate fever can be due to medications that were given perioperatively, to the trauma of surgery itself, or to infections that were present before surgery. Necrotizing fasciitis due to group A streptococci or mixed organisms may present in this period. Malignant hyperthermia is rare and presents 30 minutes to several hours following inhalational anesthesia and is characterized by extreme hyperthermia, muscle rigidity, rhabdomyolysis, electrolyte abnormalities, and hypotension. Aggressive cooling and dantrolene are the mainstays of therapy. Aspiration of acidic gastric contents during surgery can cause a chemical pneumonitis (Mendelson syndrome) that rapidly develops but is transient and does not require antibiotics. Fever due to the trauma of surgery itself usually resolves in 2–3 days, longer in more complicated operative cases and in patients with head trauma.

   B. **Acute fever (within 1 week of surgery)**—Acute fever is usually due to common causes of hospital-associated infections, such as ventilator-associated pneumonia (including aspiration pneumonia in patients with decreased gag reflex) and line infections. Noninfectious causes include alcohol withdrawal, gout, pulmonary embolism, and pancreatitis. Atelectasis following surgery is commonly invoked as a cause of postoperative fever but there is no good evidence to support a causal association between the presence or degree of atelectasis and fever.

   C. **Subacute fever (at least 1 week after surgery)**—Surgical site infections commonly present at least 1 week after surgery. The type of surgery that was performed predicts specific infectious etiologies. Patients undergoing cardiothoracic surgery may be at higher risk for pneumonia and deep and superficial sternal wound infections. Meningitis without typical signs of meningismus may complicate neurosurgical procedures. Abdominal surgery may result in deep abdominal abscesses that require drainage.

#### B. Laboratory Findings

Blood cultures are universally recommended, and chest radiographs are frequently obtained. A properly prepared sputum Gram stain and semi-quantitative sputum cultures may be useful in selected patients where there is a high pretest probability of pneumonia but multiple exclusion criteria probably limit generalizability in most patients, such as immunocompromised patients and those with drug resistance. Other diagnostic strategies will be dictated by the clinical context (eg, transthoracic echocardiogram in a patient with *S aureus* bacteremia).
Any fever in a patient with a central venous catheter should prompt the collection of blood. The best method to evaluate bacteremia is to gather at least two peripherally obtained blood cultures. Blood cultures from unidentified sites, a single blood culture from any site, or a blood culture through an existing line will often be positive for *S. epidermidis*, resulting in the inappropriate use of vancomycin. Unless two separate venipuncture cultures are obtained—not through catheters—interpretation of results is impossible and unnecessary therapy may be given. Every such “pseudobacteremia” increases laboratory costs, antibiotic use, and length of stay. Microbiologic evaluation of the removed catheter can sometimes be helpful, but only in addition to (not instead of) blood cultures drawn from peripheral sites. The differential time to positivity measures the difference in time that cultures simultaneously drawn through a catheter and a peripheral site become positive. A positive test (about 120 minutes difference in time) supports a catheter-related bloodstream infection, and a negative test may permit catheters to be retained.

### Complications

Patients who have persistent bacteremia and fever despite removal of the infected catheter may have complications such as septic thrombophlebitis, endocarditis, or metastatic foci of infection (particularly with *S. aureus*). Additional studies such as venous Doppler studies, transesophageal echocardiogram, and chest radiographs may be indicated, and 4–6 weeks of antibiotics may be needed. In the case of septic thrombophlebitis, anticoagulation with heparin is also recommended if there are no contraindications.

### Differential Diagnosis

Although most fevers are due to infections, about 25% of patients will have fever of noninfectious origin, including drug fever, nonspecific postoperative fevers (tissue damage or necrosis), hematoma, pancreatitis, pulmonary embolism, myocardial infarction, and ischemic bowel disease.

### Prevention

The concept of universal precautions emphasizes that all patients are treated as though they have a potential bloodborne transmissible disease, and thus all body secretions are handled with care to prevent spread of disease. Body substance isolation requires use of gloves whenever a health care worker anticipates contact with blood or other body secretions. Even though gloves are worn, health care workers should routinely wash their hands, since it is the easiest and most effective means of preventing hospital-associated infections. Application of a rapid drying, alcohol-based antiseptic is simple, takes less time than traditional hand washing with soap and water, is more effective at reducing hand colonization, and promotes compliance with hand decontamination.

Peripheral intravenous lines should be replaced every 3 days. Arterial lines and lines in the central venous circulation (including those placed peripherally) can be left in place indefinitely and are changed or removed when they are clinically suspected of being infected, when they are nonfunctional, or when they are no longer needed. Using sterile barrier precautions (including cap, mask, gown, gloves, and drape) is recommended while inserting central venous catheters. Silver alloy–impregnated Foley catheters reduce the incidence of catheter-associated bacteriuria, and antibiotic-impregnated (minocycline plus rifampin or chlorhexidine plus silver sulfadiazine) venous catheters reduce line infections and bacteremia. Silver-coated endotracheal tubes may reduce the incidence of ventilator-associated pneumonia. Whether the increased cost of these devices justifies their routine use should be determined by individual institutions. Catheter-related urinary tract infections and intravenous catheter-associated infections are not Medicare-reimbursable conditions.

Preoperative skin preparation with chlorhexidine and alcohol (versus povidone-iodine) has been shown to reduce the incidence of infection following surgery. Another strategy that can prevent surgical-site infections is the identification and treatment of *S. aureus* nasal carriers with 2% mupirocin nasal ointment and chlorhexidine soap. Daily bathing of ICU patients with chlorhexidine-impregnated washcloths versus soap and water may result in lower risk of catheter-associated bloodstream infections. Selective decontamination of the digestive tract with nonabsorbable or parenteral antibiotics, or both, may prevent hospital-acquired pneumonia and decrease mortality.

Attentive nursing care (positioning to prevent decubitus ulcers, wound care, elevating the head during tube feedings to prevent aspiration) is critical in preventing hospital-associated infections. In addition, monitoring of high-risk areas by hospital epidemiologists is critical in the prevention of infection. Some guidelines advocate rapid screening for MRSA on admission to acute care facilities among certain subpopulations of patients (eg, those recently hospitalized, admission to the intensive care unit, patients undergoing hemodialysis). However, it is not clear whether this strategy decreases the incidence of hospital-associated MRSA infections.

Vaccines, including hepatitis A, hepatitis B, and the varicella, pneumococcal, and influenza vaccinations, are important adjuncts. (See section below on Immunization against Infectious Diseases.)

### Treatment

#### A. Fever in an Intensive Care Unit Patient

Unless the patient has a central neurologic injury with elevated intracranial pressure or has a temperature > 41°C, there is less physiologic need to maintain euthermia. Empiric broad-spectrum antibiotics (see Table 30–5) are recommended for neutropenic and other immunocompromised patients and in patients who are clinically unstable.

#### B. Catheter-Associated Infections

Factors that inform treatment decisions include the type of catheter, the causative pathogen, the availability of alternate catheter access sites, the need for ongoing intravascular access, and the severity of disease.
In general, catheters should be removed if there is purulence at the exit site; if the organism is *S. aureus*, gram-negative rods, or *Candida* species; if there is persistent bacteremia (> 48 hours while receiving antibiotics); or if complications, such as septic thrombophlebitis, endocarditis, or other metastatic disease exist. Central venous catheters may be exchanged over a guidewire provided there is no erythema or purulence at the exit site and the patient does not appear to be septic. Methicillin-resistant, coagulase-negative staphylococci are the most common pathogens; thus, empiric therapy with vancomycin, 15 mg/kg intravenously twice daily, should be given assuming normal kidney function. Empiric gram-negative coverage may be considered in patients who are immunocompromised or who are critically ill (see Table 30–5).

Antibiotic treatment duration depends on the pathogen and the extent of disease. For uncomplicated bacteremia, 5–7 days of therapy is usually sufficient for coagulase-negative staphylococci, even if the original catheter is retained. Fourteen days of therapy is generally recommended for uncomplicated bacteremia caused by gram-negative rods, *Candida* species, and *S. aureus*. Antibiotic lock therapy involves the instillation of supratherapeutic concentrations of antibiotics with heparin in the lumen of catheters. The purpose is to achieve adequate concentrations of antibiotics to kill microbes in the biofilm. Antibiotic lock therapy can be used for catheter-related bloodstream infections caused by coagulase-negative staphylococci or enterococci and when the catheter is being retained in a salvage situation.

**When to Refer**

- Any patient with multidrug-resistant infection.
- Any patient with fungemia or persistent bacteremia.
- Patients with multisite infections.
- Patients with impaired or fluctuating kidney function for assistance with dosing of antimicrobials.
- Patients with refractory or recurrent *C. difficile* colitis.

D. Encephalitis

Encephalitis (due to herpesviruses, arboviruses, rabies virus, flaviviruses [West Nile encephalitis, Japanese encephalitis], and many others, produces disturbances of the sensorium, seizures, and many other manifestations. Patients are more ill than those with aseptic meningitis.

Cerebrospinal fluid may be entirely normal or may show some lymphocytes and in some instances (eg, herpes simplex) red cells as well. Influenza has been associated with encephalitis, but the relationship is not clear.

E. Partially Treated Bacterial Meningitis

Previous effective antibiotic therapy given for 12–24 hours will decrease the rate of positive Gram stain results by 20% and culture by 30–40% of the cerebrospinal fluid but will have little effect on cell count, protein, or glucose.

C. Aseptic Meningitis

Aseptic meningitis—a much more benign and self-limited syndrome than purulent meningitis—is caused principally by viruses, especially herpes simplex virus and the enterovirus group (including coxsackieviruses and echoviruses). Infectious mononucleosis may be accompanied by aseptic meningitis. Leptospiral infection is also usually placed in the aseptic group because of the lymphocytic cellular response and its relatively benign course. This type of meningitis also occurs during secondary syphilis and disseminated Lyme disease. Prior to the routine administration of measles–mumps–rubella (MMR) vaccines, mumps was the most common cause of viral meningitis. Drug-induced aseptic meningitis has been reported with nonsteroidal anti-inflammatory drugs, sulfonamides and certain solid organ transplant agents, including muromonab-CD3 (OKT3).

<sup>1</sup>The dose of vancomycin is 10–15 mg/kg/dose intravenously every 6 hours.

<sup>2</sup>The usual dose of cefotaxime is 2 g intravenously every 6 hours and that of ceftriaxone is 2 g intravenously every 12 hours. If the organism is sensitive to penicillin, 3–4 million units intravenously every 4 hours is given.

<sup>3</sup>The dose of ampicillin is usually 2 g intravenously every 4 hours.

<sup>4</sup>Cefepime is given in a dose of 50–100 mg/kg intravenously every 8 hours.
Occasionally, previous antibiotic therapy will change a predominantly polymorphonuclear response to a lymphocytic pleocytosis, and some of the cerebrospinal fluid findings may be similar to those seen in aseptic meningitis.

**F. Neighborhood Reaction**

As noted in Table 30–1, this term denotes a purulent infectious process in close proximity to the central nervous system that spills some of the products of the inflammatory process—white blood cells or protein—into the cerebrospinal fluid. Such an infection might be a brain abscess, osteomyelitis of the vertebrae, epidural abscess, subdural empyema, or bacterial sinusitis or mastoiditis.

**G. Noninfectious Meningeal Irritation**

Carcinomatous meningitis, sarcoidosis, systemic lupus erythematosus, chemical meningitis, and certain drugs—nonsteroidal anti-inflammatory drugs, OKT3, TMP-SMZ, and others—can also produce symptoms and signs of meningeal irritation with associated cerebrospinal fluid pleocytosis, increased protein, and low or normal glucose. Meningitis with normal cerebrospinal fluid findings occurs in the presence of other infections such as pneumonia and shigellosis.

**H. Brain Abscess**

Brain abscess presents as a space-occupying lesion; symptoms may include vomiting, fever, change of mental status, or focal neurologic manifestations. When brain abscess is suspected, a CT scan should be performed. If positive, lumbar puncture should not be performed since results rarely provide clinically useful information and herniation can occur. The bacteriology of brain abscess is usually polymicrobial and includes *S aureus*, gram-negative bacilli, streptococci, and anaerobes (including anaerobic streptococci and *Prevotella* species).

**I. Amebic Meningoencephalitis**

These infections are caused by free-living amebas and present as two distinct syndromes. The diagnosis is confirmed by culture (*Acanthamoeba* species and *Balamuthia mandrillaris*) or identification of the organism in a wet mount of cerebrospinal fluid (*Naegleria fowleri*) or on biopsy specimens. No effective therapy is available.

Primary amebic meningoencephalitis is caused by *N fowleri* and is an acute fulminant disease, usually seen in children and young adults with recent fresh water exposure, and is characterized by signs of meningeal irritation that rapidly progresses to encephalitis and death. Rare cures have been reported with intravenous and intraventricular administration of amphotericin B.

Granulomatous amebic encephalitis is caused by *Acanthamoeba* species. It is an indolent disease, frequently seen in immunocompromised patients and associated with cutaneous lesions. Central nervous system disease is characterized by headache, nausea, vomiting, cranial neuropathies, seizures, and hemiparesis. Infections with *Balamuthia* are similar to *Acanthamoeba* in that the course is subacute to chronic, but unlike *Acanthamoeba* both immunocompromised and immunocompetent persons can be affected.

**J. Health Care–Associated Meningitis**

This infection may arise as a result of invasive neurosurgical procedures (eg, craniotomy, internal or external ventricular catheters, external lumbar catheters), complicated head trauma, or from hospital-acquired bloodstream infections. In general, the microbiology is distinct from community-acquired meningitis, with gram-negative organisms (eg, *Pseudomonas*), *S aureus*, and coagulase-negative staphylococci playing a larger role.

**Clinical Findings**

**A. Symptoms and Signs**

The classic triad of fever, stiff neck, and altered mental status has a low sensitivity (44%) for bacterial meningitis. However, nearly all patients with bacterial meningitis have at least two of the following symptoms—fever, headache, stiff neck, or altered mental status.

**B. Laboratory Tests**

Evaluation of a patient with suspected meningitis includes a blood count, blood culture, lumbar puncture followed by careful study and culture of the cerebrospinal fluid, and a chest film. The fluid must be examined for cell count, glucose, and protein, and a smear stained for bacteria (and acid-fast organisms when appropriate) and cultured for pyogenic organisms and for mycobacteria and fungi when indicated. Latex agglutination tests can detect antigens of encapsulated organisms (*S pneumoniae, H influenzae, N meningitidis, and Cryptococcus neoformans*) but are rarely used except for detection of *Cryptococcus* or in partially treated patients. Polymerase chain reaction (PCR) testing of cerebrospinal fluid has been used to detect bacteria (*S pneumoniae, H influenzae, N meningitidis, M tuberculosis, B burgdorferi, and *Tropheryma whippelii*) and viruses (herpes simplex, varicella-zoster, CMV, Epstein-Barr virus, and enteroviruses) in patients with meningitis. The greatest experience is with PCR for herpes simplex and varicella-zoster, and the tests are very sensitive (>95%) and specific. Tests to detect the other organisms may not be any more sensitive than culture, but the real value is the rapidity with which results are available, ie, hours compared with days or weeks.

**C. Lumbar Puncture and Imaging**

Since performing a lumbar puncture in the presence of a space-occupying lesion (brain abscess, subdural hematoma, subdural empyema, necrotic temporal lobe from herpes encephalitis) may result in brainstem herniation, a CT scan is performed prior to lumbar puncture if a space-occupying lesion is suspected on the basis of papilledema, seizures, or focal neurologic findings. Other indications for CT scan are an immunocompromised patient or moderate to severely impaired level of consciousness. If delays are encountered in obtaining a CT scan and bacterial meningitis is suspected, blood cultures should be drawn and
antibiotics and corticosteroids administered even before cerebrospinal fluid is obtained for culture to avoid delay in treatment (Table 30–1). Antibiotics given within 4 hours before obtaining cerebrospinal fluid probably do not affect culture results.

**Treatment**

Although it is difficult to prove with existing clinical data that early antibiotic therapy improves outcome in bacterial meningitis, prompt therapy is still recommended. In purulent meningitis, the identity of the causative microorganism may remain unknown or doubtful for a few days and initial antibiotic treatment as set forth in Table 30–2 should be directed against the microorganisms most common for each age group.

The duration of therapy for bacterial meningitis varies depending on the etiologic agent: *H influenzae*, 7 days; *N meningitidis*, 3–7 days; *S pneumoniae*, 10–14 days; *L monocytogenes*, 14–21 days; and gram-negative bacilli, 21 days.

Dexamethasone therapy is recommended for adults with pneumococcal meningitis. Ten milligrams of dexamethasone administered intravenously 15–20 minutes before or simultaneously with the first dose of antibiotics and continued every 6 hours for 4 days decreases morbidity and mortality. Patients most likely to benefit from corticosteroids are those infected with gram-positive organisms (*Streptococcus pneumoniae* or *S suis*), and those who are HIV negative. It is unknown whether patients with meningitis due to *N meningitidis* and other bacterial pathogens benefit from the use of adjunctive corticosteroids. Increased intracranial pressure due to brain edema often requires therapeutic attention. Hyperventilation, mannitol (25–50 g as a bolus intravenous infusion), and even drainage of cerebrospinal fluid by repeated lumbar punctures or by placement of ventricular catheters have been used to control cerebral edema and increased intracranial pressure. Dexamethasone (4 mg intravenously every 4–6 hours) may also decrease cerebral edema.

Therapy of brain abscess consists of drainage (excision or aspiration) in addition to 3–4 weeks of systemic antibiotics directed against organisms isolated. An empiric regimen often includes metronidazole, 500 mg orally every 8 hours, plus ceftriaxone, 2 g intravenously every 12 hours, with or without vancomycin, 10–15 mg/kg/dose intravenously every 12 hours. In cases where abscesses are <2 cm in size, where there are multiple abscesses that cannot be drained, or if an abscess is located in an area where significant neurologic sequelae would result from drainage, antibiotics for 6–8 weeks without drainage can be used.

In addition to antibiotics, in cases of health care–associated meningitis associated with an external ventricular catheter, the probability of cure is increased if the catheter is removed. In infections associated with internal ventricular catheters, removal of the internal components and insertion of an external drain is recommended.

Therapy of other types of meningitis is discussed elsewhere in this book (fungal meningitis, Chapter 36; syphilis and Lyme borreliosis, Chapter 34; tuberculous meningitis, Chapter 33; herpes encephalitis, Chapter 32).

**When to Refer**

- Patients with acute meningitis, particularly if culture negative or atypical (eg, fungi, syphilis, Lyme disease, *M tuberculosis*), or if the patient is immunosuppressed.
- Patients with chronic meningitis.
- All patients with brain abscesses and encephalitis.
- Patients with suspected hospital-acquired meningitis (eg, in patients who have undergone recent neurosurgery).
- Patients with recurrent meningitis.

**When to Admit**

- Patients with suspected acute meningitis, encephalitis, and brain abscess should be admitted for urgent evaluation and treatment.
- There is less urgency to admit patients with chronic meningitis; these patients may be admitted to expedite diagnostic procedures and coordinate care, particularly if no diagnosis has been made in the outpatient setting.

**ANIMAL & HUMAN BITE WOUNDS**

**ESSENTIALS OF DIAGNOSIS**

- Cat and human bites have higher rates of infection than dog bites.
- Hand bites are particularly concerning for the possibility of closed-space infection.
- Antibiotic prophylaxis indicated for noninfected bites of the hand and hospitalization required for infected hand bites.
- All infected wounds need to be cultured to direct therapy.

**General Considerations**

About 1000 dog bite injuries require emergency department attention each day, most often in urban areas. Dog bites occur most commonly in the summer months. Biting animals are usually known by their victims, and most
bites rarely become infected because they are superficial, and wounds of the hand should generally not be sutured since a closed-space infection of the hand can result in loss of function.

C. Prophylactic Antibiotics

Prophylaxis is indicated in high-risk bites and in high-risk patients. Cat bites in any location and hand bites by any animal, including humans, should receive prophylaxis. Individuals with certain comorbidities (diabetes, liver disease) are at increased risk for severe complications and should receive prophylaxis even for low-risk bites, as should patients without functional spleens who are at increased risk for overwhelming sepsis (primarily with *Capnocytophaga* species). Amoxicillin-clavulanate (Augmentin) 500 mg orally three times daily for 5–7 days is the regimen of choice. For patients with serious allergy to penicillin, a combination of clindamycin 300 mg orally three times daily plus doxycycline 100 mg orally twice daily, or dole-strength TMP-SMZ orally twice daily, or a fluoroquinolone (ciprofloxacin 500 mg orally twice daily or levofloxacin 500–750 mg orally once daily) is recommended for 5–7 days. Moxifloxacin, a fluoroquinolone with good aerobic and anaerobic activity, may be suitable as monotherapy at 400 mg orally once daily for 5–7 days. Agents such as dicloxacillin, cephalaxin, erythromycin, and clindamycin should not be used alone because they lack activity against *Pasteurella* species. Doxycycline and TMP-SMZ have poor activity against anaerobes and should only be used in combination with clindamycin.

Because the risk of HIV transmission is so low following a bite, routine postexposure prophylaxis is not recommended. Each case should be evaluated individually and consideration for prophylaxis should be given to those who present within 72 hours of the incident, the source is known to be HIV infected, and the exposure is high risk.

D. Antibiotics for Documented Infection

For wounds that are infected, antibiotics are clearly indicated. How they are given (orally or intravenously) and the need for hospitalization are individualized clinical decisions. The most commonly encountered pathogens require treatment with either a combination of a β-lactam plus a β-lactamase inhibitor (ampicillin-sulbactam [Unasyn], 1.5–3.0 g intravenously every 6–8 hours; piperacillin-tazobactam [Zosyn], 3.375 g intravenously every 6–8 hours; or amoxicillin-clavulanate [Augmentin], 500 mg orally three times daily) or with a carbapenem (ertapenem, 1 g intravenously daily; imipenem, 500 mg intravenously every 6–8 hours; meropenem, 1 g intravenously every 8 hours). For the patient with severe penicillin allergy, a combination of clindamycin 600–900 mg intravenously every 8 hours plus a fluoroquinolone (ciprofloxacin, 400 mg intravenously every 12 hours; levofloxacin, 500–750 mg intravenously once daily) or TMP-SMZ (10 mg/kg of trimethoprim daily in two or three divided doses) is indicated. Duration of therapy is usually 2–3 weeks unless...
complications such as septic arthritis or osteomyelitis are present; if these complications are present, therapy should be extended to 4 and 6 weeks, respectively.

**E. Tetanus and Rabies**

All patients must be evaluated for the need for tetanus (see Chapter 33) and rabies (see Chapter 32) prophylaxis.

**When to Refer**

- If septic arthritis or osteomyelitis is suspected.
- For exposure to bites by dogs, cats, reptiles, amphibians, and rodents.
- When rabies is a possibility.

**When to Admit**

- Patients with infected hand bites.
- Deep bites, particularly if over joints.

---

**SEXUALLY TRANSMITTED DISEASES**

**ESSENTIALS OF DIAGNOSIS**

- All sexually transmitted diseases (STDs) have subclinical or latent periods, and patients may be asymptomatic.
- Simultaneous infection with several organisms is common.
- All patients who seek STD testing should be screened for syphilis and HIV.
- Partner notification and treatment are important to prevent further transmission and reinfection in the index case.

**General Considerations**

The most common STDs are gonorrhea,* syphilis,* human papillomavirus (HPV)-associated condyloma acuminatum, chlamydial genital infections,* herpesvirus genital infections, trichomonas vaginitis, chancroid,* granuloma inguinale, scabies, louse infestation, and bacterial vaginosis (among women who have sex with women). However, shigellosis; hepatitis A, B, and C; amebiasis; giardiasis; cryptosporidiosis; salmonellosis; and campylobacteriosis may also be transmitted by sexual (oral-anal) contact, especially in men who have sex with men. Both homosexual and heterosexual contact are risk factors for the transmission of HIV (see Chapter 31). All STDs have subclinical or latent phases that play an important role in long-term persistence of the infection or in its transmission from infected (but largely asymptomatic) persons to other contacts. Simultaneous infection by several different agents is common.

Infections typically present in one of several ways, each of which has a defined differential diagnosis, which should prompt appropriate diagnostic tests.

**A. Genital Ulcers**

Common etiologies include herpes simplex virus, primary syphilis, and chancroid. Other possibilities include lymphogranuloma venerum (see Chapter 33), granuloma inguinale caused by *Klebsiella granulomatis* (see Chapter 33), as well as lesions caused by infection with Epstein-Barr virus and HIV. Noninfectious causes are Behçet disease (see Chapter 20), neoplasia, trauma, drugs, and irritants.

**B. Urethritis with or without Urreal Discharge**

The most common infections causing urethral discharge are *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. *N gonorrhoeae* and *C trachomatis* are also frequent causes of prostatitis among sexually active men. Other sexually transmitted infections that can cause urethritis include *Mycoplasm genitalium*, *Ureaplasma urealyticum*, and *Trichomonas vaginalis*. Noninfectious causes of urethritis includes reactive arthritis with associated urethritis (Reiters syndrome).

**C. Vaginal Discharge**

Common causes of vaginitis are bacterial vaginosis (caused by overgrowth of anaerobes such as *Gardnerella vaginalis*), candidiasis, and *T vaginalis* (see Chapter 18). Less common infectious causes of vaginitis include HPV-associated condyloma acuminata and group A streptococcus. Noninfectious causes are physiologic changes related to the menstrual cycle, irritants, and lichen planus. Even though *N gonorrhoeae* and *C trachomatis* are frequent causes of cervicitis, they rarely produce vaginal discharge.

**Screening & Prevention**

All persons who seek STD testing should undergo routine screening for HIV infection, using rapid HIV-testing (if patients may not follow-up for results obtained by standard methods) or nucleic acid amplification followed by confirmatory serology (if primary HIV infection may be a possibility) as indicated. Patients in whom STDs have been diagnosed and treated (in particular, chlamydia or gonorrhea) are at a high risk for reinfection and should be encouraged to be rescreened for STDs at 3 months following the initial STD diagnosis.

---

*Reportable to public health authorities.
Asymptomatic patients often request STD screening at the time of initiating a new sexual relationship. Routine HIV testing and hepatitis B serology testing should be offered to all such patients. In sexually active women who have not been recently screened, cervical Papanicolaou testing and nucleic acid amplification testing of a urine specimen for gonorrhea and chlamydia are recommended. Among men who have sex with men, additional screening is recommended for syphilis; hepatitis A; urethral, pharyngeal, and rectal gonorrhea; as well as urethral and rectal chlamydia. Nucleic acid amplification testing is FDA-approved for testing urine for gonorrhea or chlamydia. However, the use of nucleic acid amplification testing of secretions in the rectum and pharynx has not been validated in many laboratories. There are no recommendations to screen heterosexual men for urethral chlamydia but this could be considered in STD clinics, adolescent clinics, or in correctional facilities. The periodicity of screening thereafter depends on sexual risk, but most screening should be offered at least annually to sexually active adults (particularly those 25-years-old and under). If not immune, hepatitis B vaccination is recommended for all sexually active adults, and hepatitis A vaccination in men who have sex with men. Persons between the ages of 9 and 26 may be offered vaccination against HPV.

The risk of developing an STD following a sexual assault is difficult to accurately ascertain given high rates of baseline infections and poor follow-up. Victims of assault have a high baseline rate of infection (N gonorrhoeae, 6%; C trachomatis, 10%; T vaginalis, 15%; and bacterial vaginosis, 34%), and the risk of acquiring infection as a result of the assault is significant but is often lower than the preexisting rate (N gonorrhoeae, 6–12%; C trachomatis, 4–17%; T vaginalis, 12%; syphilis, 0.5–3%; and bacterial vaginosis, 19%). Victims should be evaluated within 24 hours after the assault, and nucleic acid amplification tests for N gonorrhoeae and C trachomatis should be performed. Vaginal secretions are obtained for Trichomonas wet mount and culture, or point-of-care testing. If a discharge is present, if there is itching, or if secretions are malodorous, a wet mount should be examined for Candida and bacterial vaginosis. In addition, a blood sample should be obtained for immediate serologic testing for syphilis, hepatitis B, and HIV. Follow-up examination for STD should be repeated within 1–2 weeks, since concentrations of infecting organisms may not have been sufficient to produce a positive test at the time of initial examination. If prophylactic treatment was given (may include postexposure hepatitis B vaccination without hepatitis B immune globulin; treatment for chlamydial, gonorrheal, or trichomonal infection; and emergency contraception), tests should be repeated only if the victim has symptoms. If prophylaxis was not administered, the individual should be seen in 1 week so that any positive tests can be treated. Follow-up serologic testing for syphilis and HIV infection should be performed in 6, 12, and 24 weeks if the initial tests are negative. The usefulness of presumptive therapy is controversial, some feeling that all patients should receive it and others that it should be limited to those in whom follow-up cannot be ensured or to patients who request it.

Although seroconversion to HIV has been reported following sexual assault when this was the only known risk, this risk is believed to be low. The likelihood of HIV transmission from vaginal or anal receptive intercourse when the source is known to be HIV positive is 1 per 1000 and 5 per 1000, respectively. Although prophylactic antiretroviral therapy has not been studied in this setting, the Department of Health and Human Services recommends the prompt institution of postexposure prophylaxis with highly active antiretroviral therapy if the person seeks care within 72 hours of the assault, the source is known to be HIV positive, and the exposure presents a substantial risk of transmission.

In addition to screening asymptomatic patients with STDs, other strategies for preventing further transmission include evaluating sex partners and administering preexposure vaccination of preventable STDs to individuals at risk; other strategies include the consistent use of male and female condoms. For each patient, there are one or more sexual contacts who require diagnosis and treatment. Prompt treatment of contacts by giving antibiotics to the index case to distribute to all sexual contacts (patient-delivered therapy) is an important strategy for preventing further transmission and to prevent reinfection in the index case.

Note that vaginal spermicides and condoms containing nonoxynol-9 provide no additional protection against STDs. Male circumcision has been demonstrated to protect against HIV and HPV acquisition in heterosexual men with HIV-infected partners. Early initiation of antiretroviral therapy in HIV-infected individuals can prevent HIV acquisition in an uninfected sex partner. Also, preexposure prophylaxis with a once-daily pill containing tenofovir plus emtricitabine has been shown to be effective in preventing HIV infection among high-risk men who have sex with men.

**When to Refer**

- Patients with a new diagnosis of HIV.
- Patients with persistent, refractory or recurrent STDs, particularly when drug resistance is suspected.

**INFECTIONS IN DRUG USERS**

**ESSENTIALS OF DIAGNOSIS**

Common infections that occur with greater frequency in drug users include:

- Skin infections, aspiration pneumonia, tuberculosis.
- Hepatitis A, B, C, D; STDs; AIDS.
- Pulmonary septic emboli, infective endocarditis.
- Osteomyelitis and septic arthritis.

**General Considerations**

There is a high incidence of infection among drug users, particularly those who inject drugs. Increased risk of infection is likely associated with poor hygiene and colonization with potentially pathogenic organisms, contamination of drugs and equipment, increased sexual risk behaviors, and impaired immune defenses. The use of parenterally administered recreational drugs has increased enormously in recent years.

Skin infections are associated with poor hygiene and use of nonsterile technique when injecting drugs. *S. aureus* (including community-acquired methicillin-resistant strains) and oral flora (*Streptococcus, Eikenella, Fusobacterium, Peptostreptococcus*) are the most common organisms, with enteric gram-negatives generally more likely seen in those who inject into the groin. Cellulitis and subcutaneous abscesses occur most commonly, particularly in association with subcutaneous ("skin-popping") or intramuscular injections and the use of cocaine and heroin mixtures (usually due to ischemia). Myositis, clostridial myonecrosis, and necrotizing fasciitis occur infrequently but are life-threatening. Wound botulism in association with black tar heroin occurs sporadically but often in clusters.

Aspiration pneumonia and its complications (lung abscess, empyema, brain abscess) result from altered consciousness associated with drug use. Mixed aerobic and anaerobic mouth flora are usually involved.

Tuberculosis also occurs in drug users, and infection with HIV has fostered the spread of tuberculosis in this population. Morbidity and mortality rates are increased in HIV-infected individuals with tuberculosis. Classic radiographic findings are often absent; tuberculosis is suspected in any patient with infiltrates who does not respond to antibiotics.

Hepatitis is very common among habitual drug users and is transmissible both by the parenteral (hepatitis B, C, and D) and by the fecal-oral route (hepatitis A). Multiple episodes of hepatitis with different agents can occur.

Pulmonary septic emboli may originate from venous thrombi or right-sided endocarditis. STDs are not directly related to drug use, but the practice of exchanging sex for drugs has resulted in an increased frequency of STDs. Syphilis, gonorrhea, and chancroid are the most common.

AIDS has a high incidence among injection drug users and their sexual contacts and among the offspring of infected women (see Chapter 31).

Infective endocarditis in persons who use drugs intravenously is most commonly caused by *S. aureus*, *Candida* (usually *C. albicans* or *C. parapsilosis*), *Enterococcus faecalis*, other streptococci, and gram-negative bacteria (especially *Pseudomonas* and *Serratia marcescens*). See Chapter 33.

Other vascular infections include septic thrombophlebitis and mycotic aneurysms. Mycotic aneurysms resulting from direct trauma to a vessel with secondary infection most commonly occur in femoral arteries and less commonly in arteries of the neck. Aneurysms resulting from hematogenous spread of organisms frequently involve intracerebral vessels and thus are seen in association with endocarditis.

Osteomyelitis and septic arthritis involving vertebral bodies, sternoclavicular joints, the pubic symphysis, the sacroiliac joints, and other sites usually result from hematogenous distribution of injected organisms or septic venous thrombi. Pain and fever precede radiographic changes, sometimes by several weeks. While staphylococci—often methicillin-resistant—are common organisms, *Serratia, Pseudomonas, Candida* (often not *C. albicans*), and other pathogens rarely encountered in spontaneous bone or joint disease are found in injection drug users.

**Treatment**

A common and difficult clinical problem is management of the parenteral drug user who presents with fever. In general, after obtaining appropriate cultures (blood, urine, and sputum if the chest radiograph is abnormal), empiric therapy is begun. If the chest radiograph is suggestive of a community-acquired pneumonia (consolidation), therapy for outpatient pneumonia is begun with a third-generation cephalosporin, such as ceftriaxone, 1 g intravenously every 24 hours, plus azithromycin, 500 mg orally or intravenously every 24 hours, or doxycycline, 100 mg orally or intravenously twice daily. If the chest radiograph is suggestive of septic emboli (nodular infiltrates), therapy for presumed endocarditis is initiated, usually with vancomycin 15 mg/kg/dose every 12 hours intravenously (due to the high prevalence of MRSA and the possibility of enterococci). If the chest radiograph is normal and no focal site of infection can be found, endocarditis is presumed. While awaiting the results of blood cultures, empiric treatment with vancomycin is started. If blood cultures are positive for organisms that frequently cause endocarditis in drug users (see above), endocarditis is presumed to be present.
and treated accordingly. If blood cultures are positive for an organism that is an unusual cause of endocarditis, evaluation for an occult source of infection should go forward. In this setting, a transesophageal echocardiogram may be quite helpful since it is 90% sensitive in detecting vegetation and a negative study is strong evidence against endocarditis. If blood cultures are negative and the patient responds to antibiotics, therapy should be continued for 7–14 days (oral therapy can be given once an initial response has occurred). In every patient, careful examination for an occult source of infection (eg, genitourinary, dental, sinus, gallbladder) should be done.

**When to Refer**

- Any patient with suspected or proven infective endocarditis.
- Patients with persistent bacteremia.

**When to Admit**

- Injection drug users with fever.
- Patients with abscesses or progressive skin and soft tissue infection that require debridement.

**ACUTE INFECTIOUS DIARRHEA**

**ESSENTIALS OF DIAGNOSIS**

- **Acute diarrhea:** lasts < 2 weeks
- **Chronic diarrhea:** lasts > 2 weeks.
- **Mild diarrhea:** ≤ 3 stools per day.
- **Moderate diarrhea:** ≥ 4 stools per day with local symptoms (abdominal cramps, nausea, tenesmus).
- **Severe diarrhea:** ≥ 4 stools per day with systemic symptoms (fever, chills, dehydration).

**General Considerations**

Acute diarrhea can be caused by a number of different factors, including emotional stress, food intolerance, inorganic agents (eg, sodium nitrite), organic substances (eg, mushrooms, shellfish), drugs, and infectious agents (including viruses, bacteria, and protozoa) (Table 30–3). From a diagnostic and therapeutic standpoint, it is helpful to classify infectious diarrhea into syndromes that produce inflammatory or bloody diarrhea and those that are noninflammatory, nonbloody, or watery. In general, the term “inflammatory diarrhea” suggests colonic involvement by invasive bacteria or parasites or by toxin production. Patients complain of frequent bloody, small-volume stools, often associated with fever, abdominal cramps, tenesmus, and fecal urgency. Common causes of this syndrome include *Shigella, Salmonella, Campylobacter, Yersinia*, invasive strains of *Escherichia coli*, *E coli O157:H7* and other Shiga-toxin–producing strains of *E coli* (STEC), *Entamoeba histolytica*, and *C difficile*. Tests for fecal leukocytes or the neutrophil marker lactoferrin are frequently positive, and definitive etiologic diagnosis requires stool culture. Noninflammatory diarrhea is generally milder and is caused by viruses or toxins that affect the small intestine and interfere with salt and water balance, resulting in large-volume watery diarrhea, often with nausea, vomiting, and cramps. Common causes of this syndrome include viruses (eg, rotavirus, norovirus, astrovirus, enteric adenoviruses), vibrioses (*Vibrio cholerae*, *Vibrio parahaemolyticus*), enterotoxin-producing *E coli*, *Giardia lamblia*, cryptosporidia, and agents that can cause food-borne gastroenteritis. In developed countries, viruses (particularly norovirus) are an important cause of hospitalizations due to acute gastroenteritis among adults.

The term “food poisoning” denotes diseases caused by toxins present in consumed foods. When the incubation period is short (1–6 hours after consumption), the toxin is usually preformed. Vomiting is usually a major complaint, and fever is usually absent. Examples include intoxication from *S aureus* or *Bacillus cereus*, and toxin can be detected in the food. When the incubation period is longer—between 8 hours and 16 hours—the organism is present in the food and produces toxin after being ingested. Vomiting is less prominent, abdominal cramping is frequent, and fever is often absent. The best example of this disease is that due to *Clostridium perfringens*. Toxin can be detected in food or stool specimens.

The inflammatory and noninflammatory diarrheas discussed above can also be transmitted by food and water and usually have incubation periods between 12 and 72 hours. *Cyclospora*, cryptosporidia, and *Isospora* are protozoans capable of causing disease in both immunocompetent and immunocompromised patients. Characteristics of disease include profuse watery diarrhea that is prolonged but usually self-limited (1–2 weeks) in the immunocompetent patient but can be chronic in the compromised host. Epidemiologic features may be helpful in determining etiology. Recent hospitalization or antibiotic use suggests *C difficile*; recent foreign travel suggests *Salmonella, Shigella, Campylobacter, E coli*, or *V cholerae*; undercooked hamburger suggests *E coli*, especially O157:H7; outbreak in long-term care facility, school, or cruise ship suggests norovirus; and fried rice consumption is associated with *B cereus* toxin. Prominent features of some of these causes of diarrhea are listed in Table 30–3.

**Treatment**

**A. General Measures**

In general, most cases of acute gastroenteritis are self-limited and do not require therapy other than supportive

PCR, polymerase chain reaction.
measures. Treatment usually consists of replacement of fluids and electrolytes and, very rarely, management of hypovolemic shock and respiratory compromise. In mild diarrhea, increasing ingestion of juices and clear soups is adequate. In more severe cases of dehydration (postural lightheadedness, decreased urination), oral glucose-based rehydration solutions can be used (Ceralyte, Pedalyte).

### B. Specific Measures

When symptoms persist beyond 3–4 days, initial presentation is accompanied by fever or bloody diarrhea, or if the patient is immunocompromised, cultures of stool are usually obtained. Symptoms have often resolved by the time cultures are completed. In this case, even if a pathogen is isolated, therapy is not needed (except for *Shigella*, since the infecting dose is so small that therapy to eradicate organisms from the stool is indicated for epidemiologic reasons). If symptoms persist and a pathogen is isolated, it is reasonable to institute specific treatment even though therapy has not been conclusively shown to alter the natural history of disease for most pathogens. Exceptions include infection with *Shigella* where antibiotic therapy has been shown to shorten the duration of symptoms by 2–3 days, and *Campylobacter* infections (early therapy, within 4 days of onset of symptoms, shortens the course of disease). Conversely, antibiotic therapy for infections with *E coli* O157:H7 does not ameliorate symptoms and may increase the risk of developing hemolytic-uremic syndrome. Uncomplicated gastroenteritis due to *Salmonella* does not require therapy because the disease is usually self-limited and therapy may prolong carriage and perhaps increase relapses. Because bacteremia with complications can occur in high-risk patients, some experts have recommended therapy for *Salmonella* in patients over the age of 50, in organ transplant recipients, in those with HIV, in patients taking corticosteroids, in those with lymphoproliferative diseases, and in those with vascular grafts. Ciprofloxacin, 500 mg orally every 12 hours for 5 days, is effective in shortening the course of illness compared with placebo in patients presenting with diarrhea, whether a pathogen is isolated or not. However, because of concerns about selecting for resistant organisms (especially *Campylobacter*, where increasing resistance to fluoroquinolones has been documented and erythromycin is the drug of choice) coupled with the fact that most infectious diarrhea is self-limited, routine use of antibiotics for all patients with diarrhea is not recommended. Antibiotics should be considered in patients with evidence of invasive disease (white cells in stool, dysentery), with symptoms 3–4 days or more in duration, with multiple stools (eight to ten or more per day), and in those with impaired immune responses. Antimotility drugs are useful in mild cases. Their use should be limited to patients without fever and without dysentery (bloody stools), and they should be used in low doses because of the risk of producing toxic megacolon.

Therapeutic recommendations for specific agents can be found elsewhere in this book.
‘avian’ influenza (see Chapter 32); leptospirosis (see Chapter 34); typhoid fever (see Chapter 33); and rickettsial infections (see Chapter 32). Foreign travel is increasingly recognized as a risk factor for colonization and disease with resistant pathogens, such as extended-spectrum β-lactamases (ESBL)—producing gram-negative organisms. Systemic febrile illnesses without a diagnosis also occurs commonly, particularly in travelers returning from sub-Saharan Africa or Southeast Asia.

A. Fever and Rash
Potential etiologies include dengue, Chikungunya, viral hemorrhagic fever, leptospirosis, meningococcemia, yellow fever, typhus, *Salmonella typhi*, and acute HIV infection.

B. Pulmonary Infiltrates
Tuberculosis, ascaris, *Paragonimus*, and *Strongyloides* can all cause pulmonary infiltrates.

C. Meningoencephalitis
Etiologies include *N meningitidis*, leptospirosis, arboviruses, rabies, and (cerebral) malaria.

D. Jaundice
Consider hepatitis A, yellow fever, hemorrhagic fever, leptospirosis, and malaria.

E. Fever without Localizing Symptoms or Signs
Malaria, typhoid fever, acute HIV infection, rickettsial illness, visceral leishmaniasis, trypanosomiasis, and dengue are possible etiologies.

F. Traveler’s Diarrhea
See next section.

► Clinical Findings
Fever and rash in the returning traveler should prompt blood cultures and serologic tests based on the exposure history. The work-up of a pulmonary infiltrate should include the placement of a PPD, examination of sputum for acid-fast bacilli and possibly for ova and parasites. Patients with evidence of meningoccephalitis should receive lumbar puncture, blood cultures, thick/thin smears of peripheral blood, history-guided serologies, and a nape biopsy (if rashes is suspected). Jaundice in a returning traveler should be evaluated for hemolysis (for malaria), and the following tests should be performed: liver function tests, thick/thin smears of peripheral blood, and directed serologic testing. The work-up of traveler’s diarrhea is presented in the following section. Finally, patients with fever but no localizing signs or symptoms should have blood cultures performed. Routine laboratory studies usually include complete blood count with differential, electrolytes, liver function tests, urinalysis, and blood cultures. Thick and thin peripheral blood smears should be done (and repeated in 12–24 hours if clinical suspicion remains high) for malaria if there has been travel to endemic areas.

Other studies are directed by the results of history, physical examination, and initial laboratory tests. They may include stool for ova and parasites, chest radiograph, HIV test, and specific serologies (eg, dengue, leptospirosis, rickettsial disease, schistosomiasis, *Strongyloides*). Bone marrow biopsy to diagnose typhoid fever could be helpful in the appropriate patient.

► When to Refer
Travelers with fever, particularly if immunocompromised.

► When to Admit
Any evidence of hemorrhage, respiratory distress, hemodynamic instability, and neurologic deficits.

---

most common pathogens. Less common are *Aeromonas, Salmonella*, noncholera vibriones, *E histolytica*, and *G lamblia*. Contributory causes include unusual food and drink, change in living habits, occasional viral infections (adenoviruses or rotaviruses), and change in bowel flora. Chronic watery diarrhea may be due to amebiasis or giardiasis or, rarely, tropical sprue.

**Clinical Findings**

**A. Symptoms and Signs**

There may be up to ten or even more loose stools per day, often accompanied by abdominal cramps and nausea, occasionally by vomiting, and rarely by fever. The stools are usually watery and not associated with fever when caused by enterotoxigenic *E coli*. With invasive bacterial pathogens (*Shigella, Campylobacter, Salmonella*) stools can be bloody and fever may be present. The illness usually subsides spontaneously within 1–5 days, although 10% remain symptomatic for 1 week or longer, and symptoms persist for longer than 1 month in 2%. Traveler’s diarrhea is also a significant risk factor for developing irritable bowel syndrome.

**B. Laboratory Findings**

In patients with fever and bloody diarrhea, stool culture is indicated, but in most cases, cultures are reserved for those who do not respond to antibiotics.

**Prevention**

**A. General Measures**

Avoidance of fresh foods and water sources that are likely to be contaminated is recommended for travelers to developing countries, where infectious diarrheal illnesses are endemic.

**B. Specific Measures**

Because not all travelers will have diarrhea and because most episodes are brief and self-limited, the currently recommended approach is to provide the traveler with a supply of antimicrobials to be taken if significant diarrhea occurs during the trip. In areas where toxin-producing bacteria are the major cause of diarrhea (Latin America and Africa), loperamide (4 mg oral loading dose, then 2 mg after each loose stool to a maximum of 16 mg/d) with a single oral dose of ciprofloxacin (750 mg), levofloxacin (500 mg), or ofloxacin (200 mg), cures most cases of traveler’s diarrhea. If diarrhea is associated with bloody stools or persists despite a single dose of a fluoroquinolone, 1000 mg of azithromycin should be taken. In pregnant women and in areas where invasive bacteria more commonly cause diarrhea (Indian subcontinent, Asia, especially Thailand where fluoroquinolone-resistant *Campylobacter* is prevalent), azithromycin is the drug of choice. Rifaximin, a nonabsorbable agent, is also approved for therapy of traveler’s diarrhea at a dose of 200 mg orally three times per day or 400 mg twice a day for 3 days. Because luminal concentrations are high, but tissue levels are insufficient, it should not be used in situations where there is a high likelihood of invasive disease (eg, fever, systemic toxicity, or bloody stools). Prophylaxis is recommended for those with significant underlying disease (inflammatory bowel disease, AIDS, diabetes, heart disease in the elderly, conditions requiring immunosuppressive medications) and for those whose full activity status during the trip is so essential that even short periods of diarrhea would be unacceptable.

Prophylaxis is started upon entry into the destination country and is continued for 1 or 2 days after leaving. For stays of more than 3 weeks, prophylaxis is not recommended because of the cost and increased toxicity. For prophylaxis, numerous oral antimicrobial once-daily regimens are effective, such as norfloxacin, 400 mg; ciprofloxacin, 500 mg; or rifaximin, 200 mg. Bismuth subsalicylate is effective but turns the tongue and the stools black and can interfere with doxycycline absorption, which may be needed for malaria prophylaxis; it is rarely used.

**Treatment**

For most individuals, the affliction is short-lived, and symptomatic therapy with loperamide is all that is required, provided the patient is not systemically ill (fever ≥ 39°C) and does not have dysentery (bloody stools), in which case antimotility agents should be avoided. Packages of oral rehydration salts to treat dehydration are available over the counter in the United States (Infalyte, Pedialyte, others) and in many foreign countries.

**When to Refer**

- Cases refractory to treatment.
- Persistent infection.
- Immunocompromised patient.

**When to Admit**

Patients who are severely dehydrated or hemodynamically unstable should be admitted to the hospital.

---

**ANTIMICROBIAL THERAPY**

**SELECTED PRINCIPLES OF ANTIMICROBIAL THERAPY**

Specific steps (outlined below) are required when considering antibiotic therapy for patients. Drugs within classes, drugs of first choice, and alternative drugs are presented in Table 30–4.

**Problems in Infectious Diseases & Antimicrobial Therapy**

**Etiologic Diagnosis**

Based on the organ system involved, the organism causing infection can often be predicted. See Tables 30–5 and 30–6.

**“Best Guess”**

Select an empiric regimen that is likely to be effective against the suspected pathogens.

**Laboratory Control**

Specimens for laboratory examination should be obtained before institution of therapy to determine susceptibility.

**Clinical Response**

Based on clinical response and other data, the laboratory reports are evaluated and then the desirability of changing the regimen is considered. If the specimen was obtained from a normally sterile site (eg, blood, cerebrospinal fluid, pleural fluid, joint fluid), the recovery of a microorganism in significant amounts is meaningful even if the organism recovered is different from the clinically suspected agent, and this may force a change in treatment. Isolation of unexpected microorganisms from the respiratory tract, gastrointestinal tract, or surface lesions (sites that have a complex flora) may represent colonization or contamination, and cultures must be critically evaluated before drugs are abandoned that were judiciously selected on a “best guess” basis.

**Drug Susceptibility Tests**

Some microorganisms are predictably inhibited by certain drugs; if such organisms are isolated, they need not be tested for drug susceptibility. For example, all group A hemolytic streptococci are inhibited by penicillin. Other organisms (eg, enteric gram-negative rods) are variably susceptible and generally require susceptibility testing whenever they are isolated. Organisms that once had predictable susceptibility patterns have now become resistant and require testing. Examples include the pneumococci, which may be resistant to multiple drugs (including penicillin, macrolides, and TMP-SMZ); the enterococci, which may be resistant to penicillin, aminoglycosides, and this may force a change in treatment.

²Fluoroquinolones include ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin, and others (see text). Gemifloxacin, levofloxacin, and moxifloxacin have the best activity against gram-positive organisms, including penicillin-resistant *S pneumoniae* and methicillin-sensitive *S aureus*. Activity against enterococci and *S epidermidis* is variable.
³Erythromycin estolate is best absorbed orally but carries the highest risk of hepatitis; erythromycin stearate and erythromycin ethylsuccinate are also available.
⁴All tetracyclines have similar activity against most microorganisms. Minocycline (most likely to have *S aureus* activity), doxycycline, tetracycline have increased activity against *S aureus*.
⁵TMP-SMZ is a mixture of 1 part trimethoprim and 5 parts sulfamethoxazole.
⁶Penicillin G is preferred for parenteral injection; penicillin V for oral administration—to be used only in treating infections due to highly sensitive organisms.
⁷Infections caused by isolates with intermediate resistance may respond to high doses of penicillin, cefotaxime, or ceftriaxone. Infections caused by highly resistant strains should be treated with vancomycin. Many strains of penicillin-resistant pneumococci are resistant to macrolides, cephalosporins, tetracyclines, and TMP-SMZ.
⁸Most intravenous cephalosporins (with the exception of ceftazidime) have good activity against gram-positive cocci.
⁹Parenteral nafcillin or oxacillin, oral dicloxacillin, cloxacillin, or oxacillin.
¹⁰Addition of gentamicin indicated only for severe enterococcal infections (eg, endocarditis, meningitis).
¹¹Linezolid, daptomycin, tigecycline, quinupristin-dalfopristin should be reserved for the treatment of vancomycin resistant isolates or in patients intolerant of vancomycin.
¹²Aminoglycosides—gentamicin, tobramycin, amikacin, netilmicin—should be chosen on the basis of local patterns of susceptibility.
¹³Resistance is common and susceptibility testing should be done.
¹⁴Activity against isolates with intermediate resistance may respond to high doses of penicillin, cefotaxime, or ceftriaxone. Infections caused by highly resistant strains should be treated with vancomycin. Many strains of penicillin-resistant pneumococci are resistant to macrolides, cephalosporins, tetracyclines, and TMP-SMZ.
¹⁵Ciprofloxacin has inferior antichlamydial activity compared with levofloxacin or ofloxacin.

Key: ±, alone or combined with.

---

2. Fluoroquinolones include ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin, and others (see text). Gemifloxacin, levofloxacin, and moxifloxacin have the best activity against gram-positive organisms, including penicillin-resistant *S pneumoniae* and methicillin-sensitive *S aureus*. Activity against enterococci and *S epidermidis* is variable.
3. Erythromycin estolate is best absorbed orally but carries the highest risk of hepatitis; erythromycin stearate and erythromycin ethylsuccinate are also available.
4. All tetracyclines have similar activity against most microorganisms. Minocycline (most likely to have *S aureus* activity), doxycycline, tetracycline have increased activity against *S aureus*.
5. TMP-SMZ is a mixture of 1 part trimethoprim and 5 parts sulfamethoxazole.
6. Penicillin G is preferred for parenteral injection; penicillin V for oral administration—to be used only in treating infections due to highly sensitive organisms.
7. Infections caused by isolates with intermediate resistance may respond to high doses of penicillin, cefotaxime, or ceftriaxone. Infections caused by highly resistant strains should be treated with vancomycin. Many strains of penicillin-resistant pneumococci are resistant to macrolides, cephalosporins, tetracyclines, and TMP-SMZ.
8. Most intravenous cephalosporins (with the exception of ceftazidime) have good activity against gram-positive cocci.
9. Parenteral nafcillin or oxacillin, oral dicloxacillin, cloxacillin, or oxacillin.
10. Addition of gentamicin indicated only for severe enterococcal infections (eg, endocarditis, meningitis).
11. Linezolid, daptomycin, tigecycline, quinupristin-dalfopristin should be reserved for the treatment of vancomycin resistant isolates or in patients intolerant of vancomycin.
12. Aminoglycosides—gentamicin, tobramycin, amikacin, netilmicin—should be chosen on the basis of local patterns of susceptibility.
13. Resistance is common and susceptibility testing should be done.
14. Activity against isolates with intermediate resistance may respond to high doses of penicillin, cefotaxime, or ceftriaxone. Infections caused by highly resistant strains should be treated with vancomycin. Many strains of penicillin-resistant pneumococci are resistant to macrolides, cephalosporins, tetracyclines, and TMP-SMZ.
15. Ciprofloxacin has inferior antichlamydial activity compared with levofloxacin or ofloxacin.

Key: ±, alone or combined with.

</table>

¹Some strains may be resistant to penicillin.
²Most studies on meningitis have been with cefotaxime or ceftriaxone (see text).
³TMP-SMZ can be used to treat Listeria monocytogenes in patients allergic to penicillin in a dosage of 15–20 mg/kg/d of TMP in three or four divided doses.
⁴Depending on local drug susceptibility pattern, use tobramycin, 5 mg/kg/d, or amikacin, 15 mg/kg/d, in place of gentamicin.
⁵Levofloxacin 750 mg/d, moxifloxacin 400 mg/d.

(continued)
between susceptibility testing and clinical response, the following possibilities must be considered:

1. Selection of an inappropriate drug, drug dosage, or route of administration.
2. Failure to drain a collection of pus or to remove a foreign body.
3. Failure of a poorly diffusing drug to reach the site of infection (eg, central nervous system) or to reach intracellular phagocytosed bacteria.
4. Superinfection in the course of prolonged chemotherapy.
5. Emergence of drug-resistant organisms.
6. Participation of two or more microorganisms in the infectious process, of which only one was originally detected and used for drug selection.
7. Inadequate host defenses, including immunodeficiencies and diabetes.
8. Noninfectious causes, including drug fever, malignancy, and autoimmune disease.

and vancomycin; and extended-spectrum β-lactamase producing—E coli resistant to third-generation cephalosporins and fluoroquinolones.

Over the past several years, pharmaceutical companies have shifted away from developing and producing antibacterial medications, particularly those active against gram-negative pathogens. The lack of new drugs and increasing bacterial resistance reinforce the need to use these drugs judiciously. When culture and susceptibility results have been finalized, it is important to utilize the most narrow spectrum agent possible to decrease the selection pressure for antibacterial resistance.

Antimicrobial drug susceptibility tests may be performed on solid media as disk diffusion tests, in broth, in tubes, in wells of microdilution plates, or as E-tests (strips with increasing concentration of antibiotic). The latter three methods yield results expressed as MIC (minimal inhibitory concentration). In most infections, the MIC is the appropriate in vitro test to guide selection of an antibacterial agent. When there appear to be marked discrepancies

Table 30–6. Examples of empiric choices of antimicrobials for adult outpatient infections. (continued)

1TMP-SMZ is a fixed combination of 1 part trimethoprim and 5 parts sulfamethoxazole. Single-strength tablets: 80 mg TMP, 400 mg SMZ; double-strength tablets: 160 mg TMP, 800 mg SMZ.
2Augmentin is a combination of amoxicillin, 250 mg, 500 mg, or 875 mg, plus 125 mg of clavulanic acid. Augmentin XR is a combination of amoxicillin 1 g and clavulanic acid 62.5 mg.
3The diagnosis should be confirmed by culture before therapy. Salmonella gastroenteritis does not require therapy. For susceptible Shigella isolates, give ciprofloxacin, 0.5 g orally twice daily for 5 days; or TMP-SMZ double-strength tablets twice daily for 5 days; or ampicillin, 0.5 g orally four times daily for 5 days. For Campylobacter infection, give azithromycin, 1 g orally twice daily for 5 days; or ciprofloxacin, 0.5 g orally twice daily for 5 days. For E histolytica infection, give metronidazole, 750 mg orally three times daily for 5–10 days, followed by diiodohydroxyquin, 600 mg orally three times daily for 3 weeks.
4Fluoroquinolones and dosages include ciprofloxacin, 500 mg orally twice daily, orloxacin, 400 mg orally twice daily, levofloxacin, 500 mg orally daily.
5Fluoroquinolones with activity against S pneumoniae, including penicillin-resistant isolates, include levofloxacin (500-750 mg orally once daily) and moxifloxacin (400 mg orally once daily). Use fluoroquinolones as drug of choice if recent antibiotic use within 3 months or comorbidities present.
6MRSA, methicillin-resistant Staphylococcus aureus; TMP-SMZ, trimethoprim-sulfamethoxazole.
F. Promptness of Response

Response depends on a number of factors, including the patient (immunocompromised patients respond slower than immunocompetent patients), the site of infection (deep-seated infections such as osteomyelitis and endocarditis respond more slowly than superficial infections such as cystitis or cellulitis), the pathogen (virulent organisms such as S. aureus respond more slowly than viridans streptococci; mycobacterial and fungal infections respond slower than bacterial infections), and the duration of illness (in general, the longer the symptoms are present, the longer it takes to respond). Thus, depending on the clinical situation, persistent fever and leukocytosis several days after initiation of therapy may not indicate improper choice of antibiotics but may be due to the natural history of the disease being treated. In most infections, either a bacteriostatic or a bactericidal agent can be used. In some infections (eg, infective endocarditis and meningitis), a bactericidal agent should be used. When potentially toxic drugs (eg, aminoglycosides, fluycytosine) are used, serum levels of the drug are measured to minimize toxicity and ensure appropriate dosage. In patients with altered renal or hepatic clearance of drugs, the dosage or frequency of administration must be adjusted; it is best to measure levels in the elderly, morbidly obese patients, or those with altered kidney function when possible and adjust therapy accordingly.

G. Duration of Antimicrobial Therapy

Generally, effective antimicrobial treatment results in reversal of the clinical and laboratory parameters of active infection and marked clinical improvement. However, varying periods of treatment may be required for cure. Key factors include (1) the type of infecting organism (bacterial infections generally can be cured more rapidly than fungal or mycobacterial ones), (2) the location of the process (eg, endocarditis and osteomyelitis require prolonged therapy), and (3) the immunocompetence of the patient. Recommendations about duration of therapy are often given based on clinical experience, not prospective controlled studies of large numbers of patients.

H. Adverse Reactions and Toxicity

These include hypersensitivity reactions, direct toxicity, superinfection by drug-resistant microorganisms, and drug interactions. If the infection is life threatening and treatment cannot be stopped, the reactions are managed symptomatically or another drug is chosen that does not cross-react with the offending one (Table 30–4). If the infection is less serious, it may be possible to stop all antimicrobials and monitor the patient closely.

I. Route of Administration

Intravenous therapy is preferred for acutely ill patients with serious infections (eg, endocarditis, meningitis, sepsis, severe pneumonia) when dependable levels of antibiotics are required for successful therapy. Certain drugs (eg, fluconazole, voriconazole, rifampin, metronidazole, TMP-SMZ, and fluoroquinolones) are so well absorbed that they generally can be administered orally in seriously ill—but not hemodynamically unstable—patients.

Food does not significantly influence the bioavailability of most oral antimicrobial agents. However, the tetracyclines and the quinolones chelate multivalent cations resulting in decreased antibacterial absorption. Azithromycin capsules are associated with decreased bioavailability when taken with food and should be given 1 hour before or 2 hours after meals. Posaconazole solution should always be administered with food.

A major complication of intravenous antibiotic therapy is catheter infections. Peripheral catheters are changed every 48–72 hours to prevent phlebitis, and antimicrobial-coated central venous catheters (minocycline and rifampin, chlorhexidine and sulfadiazine) have been associated with a decreased incidence of catheter-related infections. Most of these infections present with local signs of infection (erythema, tenderness) at the insertion site. In a patient with fever who is receiving intravenous therapy, the catheter must always be considered a potential source. Small-gauge (20–23F) peripherally inserted silcone or polyurethane catheters (Per Q Cath, A-Cath, Ven-A-Cath, and others) are associated with a low infection rate and can be maintained for 3–6 months without replacement. Such catheters are ideal for long-term outpatient antibiotic therapy.

J. Cost of Antibiotics

The cost of these agents can be substantial. In addition to acquisition cost, monitoring costs, (drug levels, liver function tests, electrolytes, etc), the cost of treating adverse reactions, the cost of treatment failure, and the costs associated with drug administration must be considered.

Hypersensitivity Tests & Desensitization

Penicillin Allergy

All penicillins are cross-sensitizing and cross-reacting. The responsible antigenic determinants appear to be degradation products of penicillins, particularly penicilloic acid and products of alkaline hydrolysis (minor antigenic determinants) bound to host protein. Skin tests with penicilloylpolylysine, with minor antigenic determinants, and with degraded penicillin can identify most individuals with IgE-mediated reactions (hives, bronchospasm). Among positive reactors to skin tests, the incidence of subsequent immediate severe penicillin reactions is high. Although IgG antibodies to antigenic determinants of penicillin develop in many persons, the presence of such antibodies is not correlated with allergic reactivity (except for rare instances of
hemolytic anemia), and serologic tests have little predictive value. A history of a penicillin reaction in the past is often not reliable. Only 15–20% of patients with a history of penicillin allergy have an adverse reaction when challenged with the drug. The decision to administer penicillin or related drugs (other β-lactams) to patients with an allergic history depends on the severity of the reported reaction, the severity of the infection being treated, and the availability of alternative drugs. For patients with a history of severe reaction (anaphylaxis), alternative drugs should be used. In the rare situations when there is a strong indication for using penicillin (eg, syphilis in pregnancy) in allergic patients, desensitization can be performed. If the reaction is mild (nonurticarial rash), the patient may be rechallenged with penicillin. If the test is negative, the cephalosporin may or may be given another β-lactam antibiotic.

Allergic reactions include anaphylaxis, serum sickness (urticaria, fever, joint swelling, angioedema 7–12 days after exposure), skin rashes, fever, interstitial nephritis, cosinophilia, hemolytic anemia, other hematologic disturbances, and vasculitis. The incidence of hypersensitivity to penicillin is estimated to be 1–5% among adults in the United States. Life-threatening anaphylactic reactions are very rare (0.05%). Ampicillin produces maculopapular skin rashes more frequently than other penicillins, but many ampicillin (and other β-lactam) rashes are not allergic in origin. The non-allergic ampicillin rash usually occurs after 3–4 days of therapy, is maculopapular, is more common in patients with coexisting viral illness (especially Epstein-Barr infection), and resolves with continued therapy. The maculopapular rash may or may not reappear with rechallenge. Rarely, penicillins can induce nephritis with primary thrombotic or maculopapular skin rash or serum sickness of only 15%. IgG-mediated delayed reactions such as erythematous or maculopapular skin rash or serum sickness should be distinguished from immediate-type IgE-mediated reactions, such as urticaria, angioedema, and anaphylaxis.

Penicillin skin testing traditionally was used to identify those patients with an accelerated reaction to penicillin. This process involves the introduction of penicillin breakdown products by intradermal or prick application to detect a localized allergic reaction. At the present time, no products are available for penicillin allergy skin testing. In 2004, the only commercially available product (Pre-Pen; HollisterStier Laboratories; Spokane, Washington) was voluntarily withdrawn by the manufacturer from US and Canadian markets due to product irregularities. However, AllerQuest (West Hartford, Connecticut) is pursuing approval from the US Food and Drug Administration to manufacture and market Pre-Pen.

**Desensitization**

**A. Precautions**

1. The desensitization procedure is not innocuous—deaths from anaphylaxis have been reported. If extreme hypersensitivity is suspected, it is advisable to use an alternative structurally unrelated drug and to reserve desensitization for situations when treatment cannot be withheld and no alternative drug is available.

2. An antihistaminic drug (25–50 mg of hydroxyzine or diphenhydramine intramuscularly or orally) should be administered before desensitization is begun in order to lessen any reaction that occurs.

3. Desensitization should be conducted in an intensive care unit where cardiac monitoring and emergency endotracheal intubation can be performed.

4. Epinephrine, 1 mL of 1:1000 solution, must be ready for immediate administration.

**B. Desensitization Method**

Several methods of desensitization have been described for penicillin, including use of both oral and intravenous preparations. All methods start with very small doses of drug and gradually increase the dose until therapeutic doses are achieved. For penicillin, 1 unit of drug is given intravenously and the patient observed for 15–30 minutes. If there is no reaction, some recommend doubling the dose while others recommend increasing it tenfold every 15–30 minutes until a dosage of 2 million units is reached; then give the remainder of the desired dose.

For recommendations on skin testing and desensitization for other preparations (eg, botulism antitoxin and diphtheria antitoxin), the manufacturer’s package inserts should be consulted.

**Treatment of Reactions**

**A. Mild Reactions**

If a mild reaction occurs, drop back to the next lower dose and continue with desensitization. If a severe reaction...
occurs, administer epinephrine (see below) and discontinue the drug unless treatment is urgently needed. If desensitization is imperative, continue slowly, increasing the dosage of the drug more gradually.

**B. Severe Reactions**

If bronchospasm occurs, epinephrine, 0.3–0.5 mL of 1:1000 dilution, should be given subcutaneously every 10–20 minutes, followed by corticosteroids (250 mg of hydrocortisone or 50 mg of methylprednisolone intravenously every 6 hours for two to four doses), if needed. Hypotension should be treated with intravenous fluids (saline or colloid), epinephrine (1 mL of 1:1000 dilution in 500 mL of D5W intravenously at a rate of 0.5–5 mcg/min), and antihistamines (25–50 mg of hydroxyzine or diphenhydramine intramuscularly or orally every 6–8 hours as needed). Cutaneous reactions, manifested as urticaria or angioedema, respond to epinephrine subcutaneously and antihistamines in the doses set forth above.

**IMMUNIZATION AGAINST INFECTIOUS DISEASES**

**RECOMMENDED IMMUNIZATION OF INFANTS, CHILDREN, & ADOLESCENTS**

The recommended schedules and dosages of vaccination change often, so the manufacturer’s package inserts should always be consulted.

The schedule for active immunizations in children can be accessed at www.cdc.gov/vaccines/recs/schedules. All adolescents should see a health care provider to ensure vaccination of those who have not received varicella or hepatitis B vaccine, to make certain that a second dose of MMR has been given, to receive a booster of tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine (Tdap adolescent preparation), to receive meningococcal vaccine conjugate vaccine, to obtain HPV vaccine if not given previously, and to receive immunizations (influenza and pneumococcal vaccines) that may be indicated for certain high-risk individuals.

**RECOMMENDED IMMUNIZATION FOR ADULTS**

Immunization is one of the most important tools (along with sanitation) used to prevent morbidity and mortality from infectious diseases. In general, the administration of most vaccinations induces a durable antibody response (active immunity). In contrast, passive immunization occurs when preformed antibodies are given (e.g., immune globulin from pooled serum), resulting in temporary protection which is a less durable response. The two variants of active immunization are live attenuated vaccines (which are believed to result in an immunologic response more like natural infection), and inactivated or killed vaccines.

The schedule of vaccinations varies based on the risk of the disease being prevented by vaccination, whether a vaccine has been given previously, the immune status of the patient (probability of responding to vaccine) and safety of the vaccine (live versus killed product, as well implications for the fetus in pregnant women). Recommendations for healthy adults as well as special populations based on medical conditions are summarized in Table 30–7, which can be accessed online at www.cdc.gov/vaccines/recs/schedules.

**1. Healthy Adults**

Vaccination recommendations are made by the Advisory Committee on Immunization Practices (ACIP) of the US Centers for Disease Control and Prevention (Table 30–7). In general, all adults should be immune to diphtheria, tetanus, varicella, measles, mumps and rubella, and vaccinated if not immune. Pertussis (via Tdap) boosters should be given once to all adults younger than 65 years, including pregnant women but after the end of the second trimester. A pertussis booster should be administered to persons aged 65 years and older if there is close child contact. The following vaccines are recommended for certain adult subgroups: HPV (women and men up to age 26), herpes zoster (adults aged 60 years and older), hepatitis A (men who have sex with men, injection drug users, patients with chronic liver disease), hepatitis B (sexually active adults, injection drug users, health care workers, patients with chronic kidney and liver disease, and patients with diabetes mellitus under the age of 60 years), and meningococcal vaccination (college freshmen, military recruits, patients with asplenia and terminal complement deficiencies). Pneumococcal polysaccharide vaccination (PPSV23) should be offered to persons 65 years and older, any adult with chronic medical comorbidities, and all cigarette smokers. Influenza vaccination should be offered annually to all persons aged 6 months and older.

**2. Pregnant Women**

Given the uncertainty of risks to the fetus, vaccination during pregnancy is generally avoided with the following exceptions: tetanus (transfer of maternal antibodies across the placenta important to prevent neonatal tetanus), diphtheria, and influenza. Live vaccines are avoided during pregnancy. If the woman is pregnant and > 10 years has elapsed since tetanus and diphtheria toxoid vaccine (Td), then a Td booster vaccination should be given during the second or third trimester. ACIP also recommends prevention of pertussis in pregnant women (given the repercussions of transmission to the infant) since immunity wanes by adulthood. Women should therefore receive the combined tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine (Tdap) if possible. Tdap can be administered prior to conception, late in second trimester (> 20 weeks gestation), or in the immediate postpartum period if the mother has not previously received Tdap or if she only received Td during pregnancy.

Recommended Adult Immunization Schedule—United States - 2012

*Covered by the Vaccine Injury Compensation Program

Report all clinically significant postvaccination reactions to the Vaccine Adverse Event Reporting System (VAERS). Reporting forms and instructions on filing a VAERS report are available at www.vaers.hhs.gov or by telephone, 800-822-7967.

Information on how to file a Vaccine Injury Compensation Program claim is available at www.hrsa.gov/vaccinecompensation or by telephone, 800-338-2382. To file a claim for vaccine injury, contact the U.S. Court of Federal Claims, 717 Madison Place, N.W., Washington, D.C. 20005, telephone, 202-357-6400.

Additional information about the vaccines in this schedule, extent of available data, and contraindications for vaccination is also available at www.cdc.gov/vaccines or from the CDC-INFO Contact Center at 800-CDC-INFO (800-232-4636) in English and Spanish, 8:00 a.m. - 8:00 p.m. Eastern Time, Monday - Friday, excluding holidays.

Use of trade names and commercial sources is for identification only and does not imply endorsement by the U.S. Department of Health and Human Services.

**Notes:**
- Covered by the Vaccine Injury Compensation Program
- For all vaccines being recommended on the Adult Immunization Schedule, a vaccine series does not need to be restarted, regardless of the time that has elapsed between doses.
- Licensed combination vaccines may be used whenever any components of the combination are indicated and when the vaccine’s other components are not contraindicated.
- Detailed recommendations on all vaccines, including those used primarily for travelers or that are issued during the year, will be available at www.cdc.gov/vaccines/pubs/acip-list.htm

**Health-care personnel:**

*Recommended if some other risk factor is present (e.g., on the basis of medical, occupational, lifestyle, or other indications)*

*Contraindicated*

*No recommendation*

---

**For all persons in this category who meet the age requirements and who lack documentation of vaccination or have no evidence of previous infection.**

(continued)
Footnotes — Recommended Adult Immunization Schedule—United States - 2012

1. Additional information
   • Advisory Committee on Immunization Practices (ACIP) vaccine recommendations and additional information are available at: http://www.cdc.gov/vaccines/pubs/acip-list.htm.
   • Information on travel vaccine requirements and recommendations (e.g., for hepatitis A and B, meningococcal, and other vaccines) available at http://wwwnc.cdc.gov/travel/page/vaccinations.htm.

2. Influenza vaccination
   • Annual vaccination against influenza is recommended for all persons 6 months of age and older.
   • Persons 6 months of age and older, including pregnant women, can receive the trivalent inactivated vaccine (TIV).
   • Healthy, nonpregnant adults younger than age 50 years without high-risk medical conditions can receive either intranasally administered live, attenuated influenza vaccine (LAIV) (FluMist), or TIV. Health-care personnel who care for severely immunocompromised persons (i.e., those who require care in a protected environment) should receive TIV rather than LAIV. Other persons should receive TIV.
   • The intramuscular or intradermal administered TIV are options for adults aged 18–64 years.
   • Adults aged 65 years and older can receive the standard dose TIV or the high-dose TIV (Fluzone High-Dose).

3. Tetanus, diphtheria, and acellular pertussis (Td/Tdap) vaccination
   • Administer a one-time dose of Tdap to adults younger than age 65 years who have not received Tdap previously or for whom vaccine status is unknown to replace one of the 10-year Td boosters.
   • Tdap is specifically recommended for the following persons:
     — pregnant women more than 20 weeks’ gestation,
     — adults, regardless of age, who are close contacts of infants younger than age 12 months (e.g., parents, grandparents, or child care providers), and
     — health-care personnel.
   • Tdap can be administered regardless of interval since the most recent tetanus or diphtheria-containing vaccine.
   • Pregnant women not vaccinated during pregnancy should receive Tdap immediately postpartum.
   • Adults 65 years and older may receive Tdap.
   • Adults with unknown or incomplete history of completing a 3-dose primary vaccination series with Td-containing vaccines should begin or complete a primary vaccination series. Tdap should be substituted for a single dose of Td in the vaccination series with Tdap preferred as the first dose.
   • For unvaccinated adults, administer the first 2 doses at least 4 weeks apart and the third dose 6–12 months after the second.
   • If incompletely vaccinated (i.e., less than 3 doses), administer remaining doses.
   • Refer to the ACIP statement for recommendations for administering Td/Tdap as prophylaxis in wound management (See footnote 1).

4. Varicella vaccination
   • All adults without evidence of immunity to varicella (as defined below) should receive 2 doses of single-antigen varicella vaccine or a second dose if they have received only 1 dose.
   • Special consideration for vaccination should be given to those who
     — have close contact with persons at high risk for severe disease (e.g., health-care personnel and family contacts of persons with immunocompromising conditions) or
     — are at high risk for exposure or transmission (e.g., teachers; child care employees; residents and staff members of institutional settings, including correctional institutions; college students; military personnel; adolescents and adults living in households with children; nonpregnant women of childbearing age; and international travelers).
   • Pregnant women should be assessed for evidence of varicella immunity. Women who do not have evidence of immunity should receive the first dose of varicella vaccine upon completion or termination of pregnancy and before discharge from the health-care facility. The second dose should be administered 4–8 weeks after the first dose.
   • Evidence of immunity to varicella in adults includes any of the following:
     — documentation of 2 doses of varicella vaccine at least 4 weeks apart;
     — U.S.-born before 1980 (although for health-care personnel and pregnant women, birth before 1980 should not be considered evidence of immunity);
     — history of varicella based on diagnosis or verification of varicella by a health-care provider (for a patient reporting a history of or having an atypical case, a mild case, or both, health-care providers should seek either an epidemiologic link to a typical varicella case or to a laboratory-confirmed case or evidence of laboratory confirmation, if it was performed at the time of acute disease);
     — history of herpes zoster based on diagnosis or verification of herpes zoster by a health-care provider; or
     — laboratory evidence of immunity or laboratory confirmation of disease.
5. Human papillomavirus (HPV) vaccination

- Two vaccines are licensed for use in females, bivalent HPV vaccine (HPV2) and quadrivalent HPV vaccine (HPV4), and one HPV vaccine for use in males (HPV4).
- For females, either HPV4 or HPV2 is recommended in a 3-dose series for routine vaccination at 11 or 12 years of age, and for those 13 through 26 years of age, if not previously vaccinated.
- For males, HPV4 is recommended in a 3-dose series for routine vaccination at 11 or 12 years of age, and for those 13 through 21 years of age, if not previously vaccinated. Males 22 through 26 years of age may be vaccinated.
- HPV vaccines are not live vaccines and can be administered to persons who are immunocompromised as a result of infection (including HIV infection), disease, or medications. Vaccine is recommended for immunocompromised persons through age 26 years who did not get any or all doses when they were younger. The immune response and vaccine efficacy might be less than that in immunocompetent persons.
- Men who have sex with men (MSM) might especially benefit from vaccination to prevent condyloma and anal cancer. HPV4 is recommended for MSM through age 26 years who did not get any or all doses when they were younger.
- Ideally, vaccine should be administered before potential exposure to HPV through sexual activity; however, persons who are sexually active should still be vaccinated consistent with age-based recommendations. HPV vaccine can be administered to persons with a history of genital warts, abnormal Papanicolaou test, or positive HPV DNA test.
- A complete series for either HPV4 or HPV2 consists of 3 doses. The second dose should be administered 1–2 months after the first dose; the third dose should be administered 6 months after the first dose (at least 24 weeks after the first dose).
- Although HPV vaccination is not specifically recommended for health-care personnel (HCP) based on their occupation, HCP should receive the HPV vaccine if they are in the recommended age group.

6. Zoster vaccination

- A single dose of zoster vaccine is recommended for adults 60 years of age and older regardless of whether they report a prior episode of herpes zoster. Although the vaccine is licensed by the Food and Drug Administration (FDA) for use among and can be administered to persons 50 years and older, ACIP recommends that vaccination begins at 60 years of age.
- Persons with chronic medical conditions may be vaccinated unless their condition constitutes a contraindication, such as pregnancy or severe immunodeficiency.
- Although zoster vaccination is not specifically recommended for health-care personnel (HCP), HCP should receive the vaccine if they are in the recommended age group.

7. Measles, mumps, rubella (MMR) vaccination

- Adults born before 1957 generally are considered immune to measles and mumps. All adults born in 1957 or later should have documentation of 1 or more doses of MMR vaccine unless they have a medical contraindication to the vaccine, laboratory evidence of immunity to each of the three diseases, or documentation of provider-diagnosed measles or mumps disease. For rubella, documentation of provider-diagnosed disease is not considered acceptable evidence of immunity.
- Measles component:
  - A routine second dose of MMR vaccine, administered a minimum of 28 days after the first dose, is recommended for adults who
    - are students in postsecondary educational institutions;
    - work in a health-care facility; or
    - plan to travel internationally.
  - Persons who received inactivated (killed) measles vaccine or measles vaccine of unknown type from 1963 to 1967 should be revaccinated with 2 doses of MMR vaccine.
- Mumps component:
  - A routine second dose of MMR vaccine, administered a minimum of 28 days after the first dose, is recommended for adults who
    - are students in postsecondary educational institutions;
    - work in a health-care facility; or
    - plan to travel internationally.
  - Persons vaccinated before 1979 with either killed mumps vaccine or mumps vaccine of unknown type who are at high risk for mumps infection (e.g., persons who are working in a health-care facility) should be considered for revaccination with 2 doses of MMR vaccine.
- Rubella component:
  - For women of childbearing age, regardless of birth year, rubella immunity should be determined. If there is no evidence of immunity, women who are not pregnant should be vaccinated. Pregnant women who do not have evidence of immunity should receive MMR vaccine upon completion or termination of pregnancy and before discharge from the health-care facility.
  - Health-care personnel born before 1957:
    - For unvaccinated health-care personnel born before 1957 who lack laboratory evidence of measles, mumps, and/or rubella immunity or laboratory confirmation of disease, health-care facilities should consider routinely vaccinating personnel with 2 doses of MMR vaccine at the appropriate interval for measles and mumps or 1 dose of MMR vaccine for rubella.

(continued)
8. Pneumococcal polysaccharide (PPSV) vaccination

- Vaccinate all persons with the following indications:
  - age 65 years and older without a history of PPSV vaccination;
  - adults younger than 65 years with chronic lung disease (including chronic obstructive pulmonary disease, emphysema, and asthma); chronic cardiovascular diseases; diabetes mellitus; chronic liver disease (including cirrhosis); alcoholism; cochlear implants; cerebrospinal fluid leaks; immunocompromising conditions; and functional or anatomic asplenia (e.g., sickle cell disease and other hemoglobinopathies, congenital or acquired asplenia, splenic dysfunction, or splenectomy [if elective splenectomy is planned, vaccinate at least 2 weeks before surgery]);
  - residents of nursing homes or long-term care facilities; and
  - adults who smoke cigarettes.
- Persons with asymptomatic or symptomatic HIV infection should be vaccinated as soon as possible after their diagnosis.
- When cancer chemotherapy or other immunosuppressive therapy is being considered, the interval between vaccination and initiation of immunosuppressive therapy should be at least 2 weeks. Vaccination during chemotherapy or radiation therapy should be avoided.
- Routine use of PPSV is not recommended for American Indians/Alaska Natives or other persons younger than 65 years of age unless they have underlying medical conditions that are PPSV indications. However, public health authorities may consider recommending PPSV for American Indians/Alaska Natives who are living in areas where the risk for invasive pneumococcal disease is increased.

9. Revaccination with PPSV

- One-time revaccination 5 years after the first dose is recommended for persons 19 through 64 years of age with chronic renal failure or nephrotic syndrome; functional or anatomic asplenia (e.g., sickle cell disease or splenectomy); and for persons with immunocompromising conditions.
- Persons who received PPSV before age 65 years for any indication should receive another dose of the vaccine at age 65 years or later if at least 5 years have passed since their previous dose.
- No further doses are needed for persons vaccinated with PPSV at or after age 65 years.

10. Meningococcal vaccination

- Administer 2 doses of meningococcal conjugate vaccine quadrivalent (MCV4) at least 2 months apart to adults with functional asplenia or persistent complement component deficiencies.
- HIV-infected persons who are vaccinated should also receive 2 doses.
- Administer a single dose of meningococcal vaccine to microbiologists routinely exposed to isolates of Neisseria meningitidis, military recruits, and persons who travel to or live in countries in which meningococcal disease is hyperendemic or epidemic.
- First-year college students up through age 21 years who are living in residence halls should be vaccinated if they have not received a dose on or after their 16th birthday.
- MCV4 is preferred for adults with any of the preceding indications who are 55 years old and younger; meningococcal polysaccharide vaccine (MPSV4) is preferred for adults 56 years and older.
- Revaccination with MCV4 every 5 years is recommended for adults previously vaccinated with MCV4 or MPSV4 who remain at increased risk for infection (e.g., adults with anatomic or functional asplenia or persistent complement component deficiencies).

11. Hepatitis A vaccination

- Vaccinate any person seeking protection from hepatitis A virus (HAV) infection and persons with any of the following indications:
  - men who have sex with men and persons who use injection drugs;
  - persons working with HAV-infected primates or with HAV in a research laboratory setting;
  - persons with chronic liver disease and persons who receive clotting factor concentrates;
  - persons traveling to or working in countries that have high or intermediate endemicity of hepatitis A; and
  - unvaccinated persons who anticipate close personal contact (e.g., household or regular babysitting) with an international adoptee during the first 60 days after arrival in the United States from a country with high or intermediate endemicity. (See footnote 1 for more information on travel recommendations). The first dose of the 2-dose hepatitis A vaccine series should be administered as soon as adoption is planned, ideally 2 or more weeks before the arrival of the adoptee.
- Single-antigen vaccine formulations should be administered in a 2-dose schedule at either 0 and 6–12 months (Havrix), or 0 and 6–18 months (Vaqta). If the combined hepatitis A and hepatitis B vaccine (Twidelix) is used, administer 3 doses at 0, 1, and 6 months; alternatively, a 4-dose schedule may be used, administered on days 0, 7, and 21–30 followed by a booster dose at month 12.
12. Hepatitis B vaccination

- Vaccinate persons with any of the following indications and any person seeking protection from hepatitis B virus (HBV) infection:
  - sexually active persons who are not in a long-term, mutually monogamous relationship (e.g., persons with more than one sex partner during the previous 6 months); persons seeking evaluation or treatment for a sexually transmitted disease (STD); current or recent injection-drug users; and men who have sex with men;
  - health-care personnel and public-safety workers who are exposed to blood or other potentially infectious body fluids;
  - persons with diabetes younger than 60 years as soon as feasible after diagnosis; persons with diabetes who are 60 years or older at the discretion of the treating clinician based on increased need for assisted blood glucose monitoring in long-term care facilities, likelihood of acquiring hepatitis B infection, its complications or chronic sequelae, and likelihood of immune response to vaccination;
  - persons with end-stage renal disease, including patients receiving hemodialysis; persons with HIV infection; and persons with chronic liver disease;
  - household contacts and sex partners of persons with chronic HBV infection; clients and staff members of institutions for persons with developmental disabilities; and international travelers to countries with high or intermediate prevalence of chronic HBV infection; and
  - all adults in the following settings: STD treatment facilities; HIV testing and treatment facilities; facilities providing drug-abuse treatment and prevention services; health-care settings targeting services to injection-drug users or men who have sex with men; correctional facilities; end-stage renal disease programs and facilities for chronic hemodialysis patients; and institutions and nonresidential daycare facilities for persons with developmental disabilities.
- Administer missing doses to complete a 3-dose series of hepatitis B vaccine to those persons not vaccinated or not completely vaccinated. The second dose should be administered 1 month after the first dose; the third dose should be given at least 2 months after the second dose (and at least 4 months after the first dose). If the combined hepatitis A and hepatitis B vaccine (Twinrix) is used, give 3 doses at 0, 1, and 6 months; alternatively, a 4-dose Twinrix schedule, administered on days 0, 7, and 21–30 followed by a booster dose at month 12 may be used.
- Adult patients receiving hemodialysis or with other immunocompromising conditions should receive 1 dose of 40 µg/mL (Recombivax HB) administered on a 3-dose schedule or 2 doses of 20 µg/mL (Engerix-B) administered simultaneously on a 4-dose schedule at 0, 1, 2, and 6 months.

13. Selected conditions for which Haemophilus influenzae type b (Hib) vaccine may be used

- 1 dose of Hib vaccine should be considered for persons who have sickle cell disease, leukemia, or HIV infection, or who have anatomic or functional asplenia if they have not previously received Hib vaccine.

14. Immunocompromising conditions

- Inactivated vaccines generally are acceptable (e.g., pneumococcal, meningococcal, and influenza [inactivated influenza vaccine]), and live vaccines generally are avoided in persons with immune deficiencies or immunocompromising conditions. Information on specific conditions is available at http://www.cdc.gov/vaccines/pubs/acip-list.htm.
Influenza can be a serious infection if acquired in pregnancy, and all pregnant women should be offered influenza (inactivated) vaccination. The live attenuated (intranasal) influenza vaccine is not recommended during pregnancy.

3. HIV-Infected Adults

HIV-infected patients have impaired cellular and B cell responses. Inactivated or killed vaccinations can generally be given without any consequence, but the recipient may not be able to mount an adequate antibody response. Live or attenuated vaccines are generally avoided with some exceptions (ie, in patients with CD4+ T lymphocytes > 200 cells/mcL). Guidelines for vaccinating HIV-infected patients have been issued jointly by the Centers for Disease Control and Prevention, the US National Institutes of Health, and the HIV Medical Association of the Infectious Diseases Society of America. The following non-live vaccines are recommended for all HIV-infected patients: tetanus and diphtheria toxoid (Tdap as a booster once, followed by Td boosters every 10 years), HPV (in women and men until age 26), inactivated influenza, pneumococcal polysaccharide (PPSV23), hepatitis A (for HIV-infected men who have sex with men, injection drug users, patients with chronic liver disease), hepatitis B, and meningococcal vaccines (two doses for those at risk). Several live vaccines are now recommended for eligible HIV-infected patients with CD4+ T cells > 200 cells/mcL: measles, mumps, and rubella (MMR); varicella; and zoster. Timing of vaccination is important to optimize response. If possible, vaccination should be given early in the course of HIV-disease, or following immune reconstitution.

4. Hematopoietic Cell Transplant Recipients

Hematopoietic cell transplant (HCT) recipients have varying rates of immune reconstitution following transplantation, depending on (1) the type of chemotherapy or radiotherapy used pretransplantation (in autologous HCT), (2) the preparative regimen used for the transplant (3) whether graft-versus-host disease is present, and (4) the type of immunosuppression used posttransplantation (in allogeneic HCT). Vaccines may not work well in the posttransplant period. B cells may take 3–12 months to return to normal posttransplantation, and naïve T cells that can respond to new antigens only appear 6–12 months posttransplant. B cells of posttransplant patients treated with rituximab may take up to 6 months to fully recover after the last dose of the drug. Vaccines are therefore administered 6–12 months following transplantation with a minimum of 1 month between doses to maximize the probability of response. The following vaccines are recommended for HCT recipients: tetanus, diphtheria, and pertussis (three doses of Tdap, although full-dose DTaP currently given to children < 7 years may be more immunogenic), inactivated polio (three doses), *H influenzae* (three doses), pneumococcal vaccine (can start at 3 months posttransplant; use three doses of pneumococcal conjugate vaccine [PCV; more immunogenic but covers only 7 strains of pneumococcus], followed by the polysaccharide vaccine [PPSV23, covers 23 strains]), and inactivated influenza (annually). Patients may receive the live vaccines of MMR and varicella if at least 24 months have passed since the transplant and if they do not have graft-versus-host disease and are not receiving immunosuppressive medications. However, data supporting these recommendations are limited.

5. Solid Organ Transplant Recipients

Solid organ transplant recipients demonstrate a broad spectrum of immunosuppression, depending on the reason for and type of organ transplanted and the nature of the immunosuppression (including T-cell depleting agents during treatment of organ rejection). These factors affect the propensity for infection posttransplantation and the ability to develop antibody responses to vaccination. In many cases, the time between placing a patient on a transplant list and undergoing the transplantation takes months or years. Providers should take this opportunity to ensure that indicated vaccines are given during this pretransplant period to optimize antibody responses. If this is not possible, most experts give vaccines 3–6 months following transplantation. Live vaccines are contraindicated in the posttransplant period. The American Society of Transplantation Infectious Diseases Community of Practice last issued vaccination guidelines in 2009. The following inactivated vaccines are recommended for patients posttransplantation if not given before transplantation: tetanus and diphtheria toxoid (Tdap as a booster once if no tetanus booster in the past 10 years, followed by Td boosters every 10 years), inactivated polio, HPV (until age 26), inactivated influenza, pneumococcal polysaccharide (PPSV23), hepatitis A (for HIV-infected men who have sex with men, injection drug users, patients with chronic liver disease), hepatitis B, and meningococcal vaccines (for those at risk).

RECOMMENDED IMMUNIZATIONS FOR TRAVELERS

Individuals traveling to other countries frequently require immunizations in addition to those routinely recommended and may benefit from chemoprophylaxis against various diseases. Vaccinations against yellow fever and meningococcus are the only ones required by certain countries. These and other travel-specific vaccines are listed http://wwwnc.cdc.gov/travel/page/vaccinations.htm.

Various vaccines can be given simultaneously at different sites. Some, such as cholera, plague, and typhoid vaccine, cause significant discomfort and are best given at different times. In general, live attenuated vaccines (measles, mumps, rubella, yellow fever, and oral typhoid vaccine) should not be given to immunosuppressed individuals or household members of immunosuppressed people or to pregnant women. Immunoglobulin should not be given for 3 months before or at least 2 weeks after live virus vaccines, because it may attenuate the antibody response.

Chemoprophylaxis of malaria is discussed in Chapter 35.

**Cholera**

Because cholera among travelers is rare and the vaccine marginally effective, the World Health Organization (WHO) does not require immunization for persons traveling...
to endemic areas or to areas with recent outbreaks (eg, Haiti). No country requires vaccination for entry, but some local authorities may require documentation for entry. In such cases, a medical waiver will suffice or a single dose of the oral vaccine is usually sufficient.

Hepatitis B

The risk of hepatitis B infection for most international travelers is low. Hepatitis B vaccination should be considered for those traveling to areas with high (≥8%) or intermediate (2–7%) rates of endemic hepatitis B infection if the individual will have contact with blood or secretions, have unprotected sex, or will be using illicit drugs. Examples of high and intermediate risk areas include all of Africa and most of South Asia and the Middle East. Vaccination should begin at least 6 months before travel to allow for completion of the series.

Hepatitis A

Protection is recommended for susceptible persons traveling to areas where sanitation is poor and the risk of exposure to hepatitis A high because of contaminated food and water supplies and contact with infected persons (eg, anywhere except Canada, western Europe, Japan, Australia, and New Zealand). Either hepatitis A vaccine or immunoglobulin can be used, although vaccination is preferred. The first dose of vaccine should be given as soon as travel is considered. In healthy individuals, a single dose of vaccine administered any time prior to travel will provide adequate protection. In older patients, those who are immunocompromised, and those with chronic liver disease or other chronic medical problems who are planning to travel in 2 weeks or less should receive hepatitis A vaccine and immunoglobulin 0.02 mL/kg simultaneously at different anatomic sites. Those who choose not to receive vaccine should receive immunoglobulin.

Meningococcal Meningitis

If travel is contemplated to an area where meningococcal meningitis is epidemic (Nepal, sub-Saharan Africa, the “meningitis belt” from Senegal in the west to Ethiopia in the east, northern India) or highly endemic, vaccination with MCV4 is indicated for those 2–55 years of age, otherwise MPSV should be used. (Saudi Arabia requires immunization for pilgrims to Mecca.)

Plague

The risk of plague is so small to travelers that vaccine is no longer recommended for pilgrims to Mecca.) (Saudi Arabia requires immunization for pilgrims to Mecca.) The live attenuated plague vaccine is no longer recommended because of the risk of vaccine-associated disease and is no longer available in the United States, although it continues to be used in many other countries.

Rabies

For travelers to areas where rabies is common in domestic animals (eg, India, Asia, Mexico, Africa, areas of Central and South America), with extensive outdoor activities or certain professional activities (veterinarians, animal handlers, field biologists), preexposure prophylaxis with human diploid cell vaccine (HDCV), rabies vaccine adsorbed (RVA), or purified chick embryo cell culture (PCEC) vaccine should be considered. Chloroquine can blunt the immunologic response to rabies vaccine. If malaria prophylaxis with chloroquine (or mefloquine) is required, vaccination should be given intramuscularly (not intradermally) to ensure adequate antibody response.

Typhoid

Typhoid vaccination is recommended for travelers to developing countries (especially the Indian subcontinent, Asia, Africa, Central and South America, and the Caribbean) who will have prolonged exposure to contaminated food and water. Two preparations of approximately equal efficacy (50–75% effective) are available in the United States: (1) an oral live attenuated Ty21a vaccine supplied as enteric-coated capsules, and (2) a Vi capsular polysaccharide (Vi CPS) vaccine for parenteral use. The Ty21a vaccine is given as one capsule every other day for four doses. The capsules must be refrigerated and taken with cool liquids (37°C or less) at least 1 hour before meals. All four doses must be taken for maximum protection and should be completed 1 week before travel. It is not recommended for infants or children younger than 6 years. The Vi CPS vaccine is given as a single intramuscular injection at least 2 weeks prior to travel. It is not recommended for infants younger than 2 years. If continued or repeated exposures are anticipated, boosters are recommended every 2 years for the Vi CPS and every 5 years for the Ty21a. The live attenuated vaccine should not be used in immunosuppressed patients, including those with HIV infection.

Yellow Fever

The live attenuated yellow fever virus vaccine is administered once subcutaneously. Although the risk of yellow fever is low for most travelers, a number of countries require vaccination for all visitors and others require it for travelers to or from endemic areas (mainly equatorial Africa and parts of South and Central America). The WHO certificate requires registration of the manufacturer and the batch number of the vaccine. Vaccination is available in the United States only at approved centers; the local health
should be vaccinated. Vaccine should be given to travelers to endemic areas who will be staying at least 30 days and who are traveling during the transmission season, particularly if they are visiting rural areas. Travelers who spend < 30 days in the region should be considered for vaccination if they intend to visit areas of epidemic transmission or if extensive outdoor activities are planned in rural rice-growing areas. Of the two vaccines currently available in the United States, only one is for adults (inactivated Vero cell derived vaccine, IXIARO) aged 17 and older. The schedule is 0.5 mL intramuscularly at 0 and 28 days. Only children are eligible to receive the other vaccine (inactivated mouse brain derived vaccine, JE-VAX) given its limited supply in the United States.

VACCINE SAFETY

Most vaccines are safe to administer. In general, it is recommended that the use of live vaccines be avoided in immunocompromised patients, including pregnant women. Vaccines are generally not contraindicated in the following situations: mild, acute illness with low-grade fevers (< 40.5°C); concurrent antibiotic therapy; soreness or redness at the site; family history of adverse reactions to vaccinations. Absolute contraindications to vaccines are rare (Table 30–8).

| Measles, mumps, and rubella (MMR)

Fever will develop in about 5–15% of unimmunized individuals, and a mild rash will develop in about 5% 5–12 days after vaccination. Fever and rash are self-limiting, lasting only 2–3 days. Local swelling and induration are particularly common in individuals previously vaccinated with inactivated vaccine.

Pregnancy

Immunosuppressed persons should not be vaccinated (with the exception of asymptomatic HIV-infected individuals whose CD4 count is > 200/mcL).

History of anaphylaxis to neomycin or to related agents such as streptomycin

<table>

Presence of primary or acquired immunodeficiency state (leukemia, lymphoma, any malignant neoplasm affecting the bone marrow, HIV infection) Therapy with immunosuppressive medications (including high-dose corticosteroids) Pregnancy

Persons with an anaphylactic type reaction to gelatin or neomycin should not receive the vaccine.

---

1. The inactivated influenza vaccine can be given during any trimester.
2. The vaccine is prepared using embryonated chicken eggs.
3. MMR vaccine can be safely given to patients with a history of egg allergy even when severe.
4. Although vaccination of pregnant women is not recommended, with the currently available RA27/3 vaccine strain the congenital rubella syndrome does not occur in the offspring of those inadvertently vaccinated during pregnancy or within 3 months before conception.
Deer B. Wakefield's "autistic enterocolitis" under the microscope. BMJ. 2010 Apr 15;340:c1127. [PMID: 20395277]

**ESSENTIALS OF DIAGNOSIS**

- Risk factors: sexual contact with an infected person, parenteral exposure to infected blood by transfusion or needle sharing, perinatal exposure.
- Prominent systemic complaints such as sweats, diarrhea, weight loss, and wasting.
- Opportunistic infections due to diminished cellular immunity—often life-threatening.
- Aggressive cancers, particularly Kaposi sarcoma and extranodal lymphoma.
- Neurologic manifestations, including dementia, aseptic meningitis, and neuropathy.

**General Considerations**

When AIDS was first recognized in the United States in 1981, cases were identified by finding severe opportunistic infections such as *Pneumocystis* pneumonia that indicated profound defects in cellular immunity in the absence of other causes of immunodeficiency. When HIV was identified as the cause of the syndrome, it became obvious that severe opportunistic infections and unusual neoplasms were at one end of a spectrum of disease, while healthy seropositive individuals were at the other end.

The Centers for Disease Control and Prevention (CDC) AIDS case definition (Table 31–1) includes opportunistic infections and malignancies that rarely occur in the absence of severe immunodeficiency (eg, *Pneumocystis* pneumonia, central nervous system lymphoma). It also classifies persons as having AIDS if they have positive HIV serology and certain infections and malignancies that can occur in immunocompetent hosts but that are more common among persons infected with HIV (pulmonary tuberculosis, invasive cervical cancer). Several nonspecific conditions, including dementia and wasting (documented weight loss)—in the presence of a positive HIV serology—are considered AIDS. The definition includes criteria for both definitive and presumptive diagnoses of certain infections and malignancies. Finally, persons with positive HIV serology who have ever had a CD4 lymphocyte count below 200 cells/mcL or a CD4 lymphocyte percentage below 14% are considered to have AIDS. Inclusion of persons with low CD4 counts as AIDS cases reflects the recognition that immunodeficiency is the defining characteristic of AIDS. The choice of a cutoff point at 200 cells/mcL is supported by several cohort studies showing that AIDS will develop within 3 years in over 80% of persons with counts below this level in the absence of effective antiretroviral therapy (ART). The 1993 definition was also expanded to include persons with positive HIV serology and pulmonary tuberculosis (see Figure 9–5), recurrent pneumonia, and invasive cervical cancer. The prognosis of persons with HIV/AIDS has dramatically improved due to the introduction of highly active antiretroviral therapy (HAART) in the mid 1990s. One consequence is that fewer persons with HIV ever develop an infection or malignancy or have a low enough CD4 count to classify them as having AIDS, which means that the CDC definition has become a less useful measure of the impact of HIV/AIDS in the United States. Conversely, persons in whom AIDS had been diagnosed based on a serious opportunistic infection, malignancy, or immunodeficiency may now be markedly healthier, with high CD4 counts, due to the use of HAART. Therefore, the Social Security Administration as well as most social service agencies focus on functional assessment for determining eligibility for benefits rather than the simple presence or absence of an AIDS-defined illness.

**Epidemiology**

The modes of transmission of HIV are similar to those of hepatitis B, in particular with respect to sexual, parenteral, and vertical transmission. Although certain sexual practices (eg, receptive anal intercourse) are significantly riskier than other sexual practices (eg, oral sex), it is difficult to quantify per-contact risks. The reason is that studies of sexual transmission of HIV show that most people at risk for HIV infection engage in a variety of sexual practices and have sex with multiple persons, only some of whom may

There are an estimated 1,106,400 Americans infected with HIV, about 51,000 new infections each year and an estimated 468,578 persons in the United States living with AIDS. Of those, 76% are men, of whom 60% were exposed through male-to-male sexual contact, 18% were exposed through injection drug use, 11% were exposed through heterosexual contact, and 8% were exposed through male-to-male sexual contact and injection drug use. Women account for 23% of living persons with HIV infection, of whom 66% were infected through heterosexual contact and 32% were exposed through injection drug use. Children account for < 1% of living cases. African Americans have been disproportionately hard hit by the epidemic. The estimated rate of new AIDS cases in the United States per 100,000 adult/adolescent population is 59.2 among African Americans, 20.4 among Latinos, 8.6 among native Americans and native Alaskans, 6.1 among whites, 4.3 among Asians, and 22.3 among Pacific Islanders.

In general, the progression of HIV-related illness is similar in men and women. However, there are some important differences. Women are at risk for gynecologic complications of HIV, including recurrent candidal vaginitis, pelvic inflammatory disease, and cervical dysplasia. Violence directed against women, pregnancy, and frequent occurrence of drug use and poverty all complicate the treatment of HIV-infected women. Although "safer sex" campaigns dramatically decreased the rates of seroconversions among men who have sex with men (MSM) living in metropolitan areas in the United States by the mid 1980s, relapse to unsafe sexual practices among MSM in several large cities in the United States and in western Europe has been observed. The higher rates of unsafe sex appear to be related to decreased concern about acquiring HIV due to the availability of HAART. Decreased interest in following safer sex recommendations and increasing use of crystal methamphetamine among certain risk groups also appears to be playing a role in the increased unsafe sex rates.

Worldwide there are an estimated 33 million persons infected with HIV, with heterosexual spread being the most common mode of transmission for men and women. In Central and East Africa, in some urban areas, as many as one-third of sexually active adults are infected. The reason for the greater risk for transmission with heterosexual intercourse in Africa and Asia than in the United States may relate to cofactors such as general health status, the presence of genital ulcers, relative lack of male circumcision, the number of sexual partners, and different HIV serotypes.
Etiology

HIV, like other retroviruses, depends on a unique enzyme, reverse transcriptase (RNA-dependent DNA polymerase), to replicate within host cells. The other major pathogenic human retrovirus, human T cell lymphotropic/leukemia virus (HTLV)-I, is associated with lymphoma, while HIV is not known to be directly oncogenic. The HIV genomes contain genes for three basic structural proteins and at least five other regulatory proteins; gag codes for group antigen proteins, pol codes for polymerase, and env codes for the external envelope protein. The greatest variability in strains of HIV occurs in the viral envelope. Since neutralizing activity is found in antibodies directed against the envelope, this variability presents problems for vaccine development.

In addition to the classic AIDS virus (HIV-1), a group of related viruses, HIV-2, has been isolated in West African patients. HIV-2 has the same genetic organization as HIV-1, but there are significant differences in the envelope glycoproteins. Some infected individuals exhibit AIDS-like illnesses, but the rate of progression in individuals infected with HIV-2 appears to be slower than that of HIV-1 infection. HIV-2 remains relatively rare in the United States but has become more common in Western Europe due to immigration from endemic areas. Cases have been documented in which AIDS-like illnesses have occurred in the absence of HIV infection or other known infectious causes of immunodeficiency.

Pathogenesis

The hallmark of symptomatic HIV infection is immunodeficiency caused by continuing viral replication. The virus can infect all cells expressing the T4 (CD4) antigen, which HIV uses to attach to the cell. Chemokine coreceptors (CCR5 or CXCR4, or both) are required for virus entry, and individuals with CCR5 deletions (ie, “delta 32”) are less likely to become infected and, once infected, the disease is more likely to progress slowly. Once it enters a cell, HIV can replicate and cause cell fusion or death. A latent state is also established, with integration of the HIV genome into the cell’s genome. The cell principally infected is the CD4 (helper-inducer) lymphocyte, which directs many other cells in the immune network. With increasing duration of infection, the number of CD4 lymphocytes falls. Some of the immunologic defects, however, are explained not by quantitative abnormalities of lymphocyte subsets but by qualitative defects in CD4 responsiveness induced by HIV.

Other cells in the immune network that are infected by HIV include B lymphocytes and macrophages. The defect in B cells is partly due to disordered CD4 lymphocyte function. These direct and indirect effects can lead to generalized hypergammaglobulinemia and can also depress B cell responses to new antigen challenges. Because of these defects, the immunodeficiency of HIV is mixed. Elements of humoral and cellular immunodeficiency are present, especially in children. Macrophages act as a reservoir for HIV and serve to disseminate it to other organ systems (eg, the central nervous system).

Apart from the immunologic effects of HIV, the virus can also directly cause a variety of neurologic effects. Neuropathology largely results from the release of cytokines and other neurotoxins by infected macrophages. Perturbations of excitatory neurotransmitters and calcium flux may contribute to neurologic dysfunction. Direct HIV infection of renal tubular cells and gastrointestinal epithelium may contribute to these organ system manifestations of infection.

Pathophysiology

Clinically, the syndromes caused by HIV infection are usually explicable by one of three known mechanisms: immunodeficiency, autoimmunity, and allergic and hypersensitivity reactions.

A. Immunodeficiency

Immunodeficiency is a direct result of the effects of HIV upon immune cells. A spectrum of infections and neoplasms is seen, as in other congenital or acquired immunodeficiency states. Two remarkable features of HIV immunodeficiency are the low incidence of certain infections such as listeriosis and aspergillosis and the frequent occurrence of certain neoplasms such as lymphoma or Kaposi sarcoma. This latter complication has been seen primarily in MSM or in bisexual men, and its incidence steadily declined through the first 15 years of the epidemic. A herpesvirus (KSHV or HHV-8) is the cause of Kaposi sarcoma.

B. Autoimmunity/Allergic and Hypersensitivity Reactions

Autoimmunity can occur as a result of disordered cellular immune function or B lymphocyte dysfunction. Examples of both lymphocytic infiltration of organs (eg, lymphocytic interstitial pneumonitis) and autoantibody production (eg, immunologic thrombocytopenia) occur. These phenomena may be the only clinically apparent disease or may coexist with obvious immunodeficiency. Moreover, HIV-infected individuals appear to have higher rates of allergic reactions to unknown allergens as seen with eosinophilic pustular folliculitis (“itchy red bump syndrome”) as well as increased rates of hypersensitivity reactions to medications (for example, the fever and sunburn-like rash seen with trimethoprim-sulfamethoxazole reactions).

Clinical Findings

The complications of HIV-related infections and neoplasms affect virtually every organ. The general approach to the HIV-infected person with symptoms is to evaluate the organ systems involved, aiming to diagnose treatable conditions rapidly. As can be seen in Figure 31–1, the CD4 lymphocyte count provides very important prognostic information. Certain infections may occur at any CD4 count, while others rarely occur unless the CD4 lymphocyte count has dropped below a certain level. For example, a patient with a CD4 count of 600 cells/mcL, cough, and
HIV Infection & AIDS

Specific tests for HIV include antibody and antigen detection (Table 31–2). Conventional HIV antibody testing is done by ELISA. Positive specimens are then confirmed by a different method (eg, Western blot). The sensitivity of screening serologic tests is > 99.9%. The specificity of positive results by two different techniques approaches 100% even in low-risk populations. False-positive screening tests may occur as normal biologic variants or in association with recent influenza vaccination or other disease states, such as connective tissue disease. These are usually detected by negative confirmatory tests. Molecular biology techniques (PCR) show a small incidence of individuals (< 1%) who are infected with HIV for up to 36 months without generating an antibody response. However, antibodies that are detectable by screening serologic tests will develop in 95% of persons within 6 weeks after infection.

Rapid HIV antibody tests provide results within 10–20 minutes and can be performed in clinician offices, including by personnel without laboratory training and without a Clinical Laboratory Improvement Amendment (CLIA) approved laboratory. Persons who test positive on a rapid test should be told that they may be HIV-infected or their test may be falsely reactive. Standard testing (ELISA with Western blot confirmation) should be performed to distinguish these two possibilities. Rapid testing is particularly helpful in settings where a result is needed immediately (eg, a woman in labor who has not recently been tested for HIV) or when the patient is unlikely to return for a result.

A. Symptoms and Signs

Many individuals with HIV infection remain asymptomatic for years even without ART, with a mean time of approximately 10 years between infection and development of AIDS. When symptoms occur, they may be remarkably protean and nonspecific. Since virtually all the findings may be seen with other diseases, a combination of complaints is more suggestive of HIV infection than any one symptom.

Physical examination may be entirely normal. Abnormal findings range from completely nonspecific to highly specific for HIV infection. Those that are specific for HIV infection include hairy leukoplakia of the tongue, disseminated Kaposi sarcoma, and cutaneous bacillary angiomatosis. Generalized lymphadenopathy is common early in infection.

The specific presentations and management of the various complications of HIV infection are discussed under the Complications section below.

B. Laboratory Findings

Figure 31–1. Relationship of CD4 count to development of opportunistic infections. MAC, Mycobacterium avium complex; CMV, cytomegalovirus; CNS, central nervous system.

fever may have a bacterial pneumonia but would be very unlikely to have Pneumocystis pneumonia.
Several laboratory markers are available to provide prognostic information and guide therapy decisions (Table 31–2). The most widely used marker is the absolute CD4 lymphocyte count. As counts decrease, the risk of serious opportunistic infection over the subsequent 3–5 years increases (Figure 31–1).

There are many limitations to using the CD4 count, including diurnal variation, depression with intercurrent illness, and intralaboratory and interlaboratory variability. Therefore, the trend is more important than a single determination. The frequency of performance of counts depends on the patient’s health status and whether or not they are receiving antiretroviral treatment. Patients not receiving treatment whose CD4 counts are substantially above the threshold for initiation of antiviral therapy (500 cells/ml) should have counts performed every 6 months. Those who have counts near or below 500 cells/ml should have counts performed every 3 months. For patients receiving ART, with undetectable viral loads, and CD4 counts > 350 cells/ml, CD4 counts need only be performed every 3–6 months. In patients who have detectable viral loads, CD4 counts should be performed every 3 months to evaluate the need for a change in therapy or for initiation of *P jiroveci* prophylactic therapy when the CD4 count drops below 200 cells/ml, or initiation of *M avium* prophylaxis when the CD4 count drops below 75–100 cells/ml. Some studies suggest that the percentage of CD4 lymphocytes is a more reliable indicator of prognosis than the absolute counts because the percentage does not depend on calculating a manual differential. While the CD4 count measures immune dysfunction, it does not provide a measure of how actively HIV is replicating in the body. HIV viral load tests (discussed below) assess the level of viral replication and provide useful prognostic information that is independent of the information provided by CD4 counts.

### Differential Diagnosis

HIV infection may mimic a variety of other medical illnesses. Specific differential diagnosis depends on the mode of presentation. In patients presenting with constitutional symptoms such as weight loss and fevers, differential considerations include cancer, chronic infections such as tuberculosis and endocarditis, and endocrinologic diseases such as hyperthyroidism. When pulmonary processes dominate the presentation, acute and chronic lung infections must be considered as well as other causes of diffuse interstitial pulmonary infiltrates. When neurologic disease is the mode of presentation, conditions that cause mental status changes or neuropathy—eg, alcoholism, liver disease, kidney dysfunction, thyroid disease, and vitamin deficiency—should be considered. If a patient presents with headache and a cerebrospinal fluid pleocytosis, other causes of chronic meningitis enter the differential. When diarrhea is a prominent complaint, infectious enterocolitis, antibiotic-associated colitis, inflammatory bowel disease, and malabsorptive symptoms must be considered.

### Complications

#### A. Systemic Complaints

Fever, night sweats, and weight loss are common symptoms in HIV-infected patients and may occur without a complicating opportunistic infection. Patients with persistent fever and no localizing symptoms should nonetheless be carefully examined, and evaluated with a chest radiograph (*Pneumocystis* pneumonia can present without respiratory symptoms), bacterial blood cultures if the fever is > 38.5 °C, serum cryptococcal antigen, and mycobacterial cultures of the blood. Sinus CT scans or sinus radiographs should be considered to evaluate occult sinusitis. If these studies are
normal, patients should be observed closely. Antipyretics are useful to prevent dehydration.

1. Weight loss—Weight loss is a particularly distressing complication of long-standing HIV infection. Patients typically have disproportionate loss of muscle mass, with maintenance or less substantial loss of fat stores. The mechanism of HIV-related weight loss is not completely understood but appears to be multifactorial.

A. Presentation—AIDS patients frequently suffer from anorexia, nausea, and vomiting, all of which contribute to weight loss by decreasing caloric intake. In some cases, these symptoms are secondary to a specific infection, such as viral hepatitis. In other cases, however, evaluation of the symptoms yields no specific pathogen, and it is assumed to be due to a primary effect of HIV. Malabsorption also plays a role in decreased caloric intake. Patients may suffer diarrhea from infections with bacterial, viral, or parasitic agents. Exacerbating the decrease in caloric intake, many AIDS patients have an increased metabolic rate. This increased rate has been shown to exist even among asymptomatic HIV-infected persons, but it accelerates with disease progression and secondary infection. AIDS patients with secondary infections also have decreased protein synthesis, which makes maintaining muscle mass difficult.

B. Management—Several strategies have been developed to slow AIDS wasting. Effective fever control decreases the metabolic rate and may slow the pace of weight loss, as does treating the underlying opportunistic infection. Food supplementation with high-calorie drinks may enable patients with not much appetite to maintain their intake. Selected patients with otherwise good functional status and weight loss due to unrelenting nausea, vomiting, or diarrhea may benefit from total parenteral nutrition (TPN). It should be noted, however, that TPN is more likely to increase fat stores than to reverse the muscle wasting process.

Two pharmacologic approaches for increasing appetite and weight gain are the progesterational agent megestrol acetate (80 mg orally four times a day) and the antiemetic agent dronabinol (2.5–5 mg orally three times a day). Side effects from megestrol acetate are rare, but thromboembolic phenomena, edema, nausea, vomiting, and rash have been reported. Euphoria, dizziness, paranoia, and somnolence and even nausea and vomiting have been reported in 3–10% of patients using dronabinol. Dronabinol contains only one of the active ingredients in smoked marijuana, and many patients report better relief of nausea and improvement of appetite with smoking marijuana. Thirteen states allow patients to obtain marijuana for medicinal purposes with a letter of recommendation from their doctor. However, the use and sale of marijuana is still illegal under federal law. The Supreme Court has ruled that physicians cannot be prosecuted for recommending marijuana to their patients (it would be an infringement of freedom of speech). Therefore, while a physician’s recommendation may not completely protect patients, letters decrease the chance that patients will be prosecuted for use of marijuana. Unfortunately, neither megestrol acetate nor dronabinol increases lean body mass.

Two regimens that have resulted in increases in lean body mass are growth hormone and anabolic steroids. Growth hormone at a dose of 0.1 mg/kg/d (up to 6 mg) subcutaneously for 12 weeks has resulted in modest increases in lean body mass. Treatment with growth hormone can cost as much as $10,000 per month. Anabolic steroids also increase lean body mass among HIV-infected patients. They seem to work best for patients who are able to do weight training. The most commonly used regimens are testosterone enanthate or testosterone cypionate (100–200 mg intramuscularly every 2–4 weeks). Testosterone transdermal system (apply 5 mg system each evening) and testosterone gel (1%; apply a 5-g packet [50 mg testosterone] to clean, dry skin daily) are also available. The anabolic steroid oxandrolone (20 mg orally in two divided doses) has also been found to increase lean body mass.

2. Nausea—Nausea leading to weight loss is sometimes due to esophageal candidiasis. Patients with oral candidiasis and nausea should be empirically treated with an oral antifungal agent. Patients with weight loss due to nausea of unclear origin may benefit from use of antiemetics prior to meals (prochlorperazine, 10 mg three times daily; metoclopramide, 10 mg three times daily; or ondansetron, 8 mg three times daily). Dronabinol (5 mg three times daily) can also be used to increase appetite. Depression and adrenal insufficiency are two potentially treatable causes of weight loss.

B. Pulmonary Disease

1. Pneumocystis pneumonia—(See also discussions in Chapter 36.) Pneumocystis jiroveci pneumonia is the most common opportunistic infection associated with AIDS. Pneumocystis pneumonia may be difficult to diagnose because the symptoms—fever, cough, and shortness of breath—are nonspecific. Furthermore, the severity of symptoms ranges from fever and no respiratory symptoms through mild cough or dyspnea to frank respiratory distress.

Hypoxemia may be severe, with a PaO₂ < 60 mm Hg. The cornerstone of diagnosis is the chest radiograph. Diffuse or peripheral infiltrates are most characteristic, but only two-thirds of patients with Pneumocystis pneumonia have this finding. Normal chest radiographs are seen in 5–10% of patients with Pneumocystis pneumonia, while the remainder have atypical infiltrates. Apical infiltrates are commonly seen among patients with Pneumocystis pneumonia who have been receiving aerosolized pentamidine prophylaxis. Large pleural effusions are uncommon with Pneumocystis pneumonia; their presence suggests bacterial pneumonia, other infections such as tuberculosis, or pleural Kaposi sarcoma.

Definitive diagnosis can be obtained in 50–80% of cases by Wright-Giemsa stain or direct fluorescence antibody (DFA) test of induced sputum. Sputum induction is performed by having patients inhale an aerosolized solution of 3% saline produced by an ultrasonic nebulizer. Patients should not eat for at least 8 hours and should not use toothpaste or mouthwash prior to the procedure since they can interfere with test interpretation. The next step for
patients with negative sputum examinations in whom *Pneumocystis* pneumonia is still suspected should be bronchoalveolar lavage. This technique establishes the diagnosis in over 95% of cases.

In patients with symptoms suggestive of *Pneumocystis* pneumonia but with negative or atypical chest radiographs and negative sputum examinations, other diagnostic tests may provide additional information in deciding whether to proceed to bronchoalveolar lavage. Elevation of serum lactate dehydrogenase occurs in 95% of cases of *Pneumocystis* pneumonia, but the specificity of this finding is at best 75%. A serum β-glucan test is more sensitive and specific test for *Pneumocystis* pneumonia compared with serum lactate dehydrogenase and may avoid more invasive tests when used in the appropriate clinical setting. Either a normal diffusion capacity of carbon monoxide (DLCO) or a high-resolution CT scan of the chest that demonstrates no interstitial lung disease makes the diagnosis of *Pneumocystis* pneumonia very unlikely. In addition, a CD4 count > 250 cells/mcL within 2 months prior to evaluation of respiratory symptoms makes a diagnosis of *Pneumocystis* pneumonia unlikely; only 1–5% of cases occur above this CD4 count level (Figure 31–1). This is true even if the patient previously had a CD4 count lower than 200 cells/mcL but has had an increase with ART. Pneumothoraces can be seen in HIV-infected patients with a history of *Pneumocystis* pneumonia, especially if they have received aerosolized pentamidine treatment.

2. Other infectious pulmonary diseases—

A. Presentation—Other infectious causes of pulmonary disease in AIDS patients include bacterial, mycobacterial, and viral pneumonias. Community-acquired pneumonia is the most common cause of pulmonary disease in HIV-infected persons. An increased incidence of pneumococcal pneumonia with septicemia and *Haemophilus influenzae* pneumonia has been reported. *Pseudomonas aeruginosa* is an important respiratory pathogen in advanced disease and, more rarely, pneumonia from *Rhodococcus equi* infection can occur. The incidence of infection with *Mycobacterium tuberculosis* has markedly increased in metropolitan areas because of HIV infection as well as homelessness. Tuberculosis occurs in an estimated 4% of persons in the United States who have AIDS. Apical infiltrates and disseminated disease occur more commonly than among immunocompetent persons. Although a purified protein derivative (PPD) test should be performed on all HIV-infected persons in whom a diagnosis of tuberculosis is being considered, the lower the CD4 cell count, the greater the likelihood of anergy. Because “anergy” skin test panels do not accurately classify those patients who are infected with tuberculosis but unreactive to the PPD, they are not recommended.

B. Management—Treatment of HIV-infected persons with active tuberculosis is similar to treatment of HIV-uninfected tubercular individuals (see Figure 31–1). However, rifampin should not be given to patients receiving a boosted protease inhibitor (PI)-regimen. In these cases, rifabutin may be substituted, but it may require dosing modifications depending on the antiretroviral regimen. Multidrug-resistant tuberculosis has been a major problem in several metropolitan areas of the developed world, and reports from South Africa of “extremely resistant” tuberculosis in AIDS patients is a growing global concern. Noncompliance with prescribed antituberculous drugs is a major risk factor. Several of the reported outbreaks appear to implicate nosocomial spread. The emergence of drug resistance makes it essential that antibiotic sensitivities be performed on all positive cultures. Drug therapy should be individualized. Patients with multidrug-resistant *M tuberculosis* infection should receive at least three drugs to which their organism is sensitive. Atypical mycobacteria can cause pulmonary disease in AIDS patients with or without preexisting lung disease and responds variably to treatment. Making a distinction between *M tuberculosis* and atypical mycobacteria requires culture of sputum specimens. If culture of the sputum produces acid-fast bacilli, definitive identification may take several weeks using traditional techniques. DNA probes allow for presumptive identification usually within days of a positive culture. While awaiting definitive diagnosis, clinicians should err on the side of treating patients as if they have *M tuberculosis* infection. In cases in which the risk of atypical mycobacteria is very high (eg, a person without risk for tuberculosis exposure with a CD4 count under 50 cells/mcL—see Figure 31–1), clinicians may wait for definitive diagnosis if the person is smear-negative for acid-fast bacilli, clinically stable, and not living in a communal setting. Isolation of cytomegalovirus (CMV) from bronchoalveolar lavage fluid occurs commonly in AIDS patients but does not establish a definitive diagnosis. Diagnosis of CMV pneumonia requires biopsy; response to treatment is poor. Histoplasmosis, coccidioidomycosis, and cryptococcal disease as well as more common respiratory viral infections should also be considered in the differential diagnosis of unexplained pulmonary infiltrates.

3. Noninfectious pulmonary diseases—

A. Presentation—Noninfectious causes of lung disease include Kaposi sarcoma, non-Hodgkin lymphoma, and interstitial pneumonitis. In patients with known Kaposi sarcoma, pulmonary involvement complicates the course in approximately one-third of cases. However, pulmonary involvement is rarely the presenting manifestation of Kaposi sarcoma. Non-Hodgkin lymphoma may involve the lung as the sole site of disease but more commonly involves other organs as well, especially the brain, liver, and gastrointestinal tract. Both of these processes may show nodular or diffuse parenchymal involvement, pleural effusions, and mediastinal adenopathy on chest radiographs.

Nonspecific interstitial pneumonitis may mimic *Pneumocystis* pneumonia. Lymphocytic interstitial pneumonitis seen in lung biopsies has a variable clinical course. Typically, these patients present with several months of mild cough and dyspnea; chest radiographs show interstitial infiltrates. Many patients with this entity undergo transbronchial biopsies in an attempt to diagnose *Pneumocystis*
patients may require referral to an otolaryngologist for there is not a response to first-line antibiotics. Some orally daily). In patients with advanced immunodeficiency, may be required. For patients not responding to amoxicillin- (600 mg orally twice daily) to decrease sinus congestion (3–6 weeks) with an antibiotic and guaifenesin space-occupying lesion in HIV-infected patients. Headache, —

1. Toxoplasmosis
Toxoplasma. Typically, toxoplasmosis appears as multiple contrast-enhancing lesions on CT scan. Lesions tend to be peripheral, with a predilection for the basal ganglia.

Single lesions are atypical of toxoplasmosis. When a single lesion has been detected by CT scanning, MRI scanning may reveal multiple lesions because of its greater sensitivity. If a patient has a single lesion on MRI and is neurologically stable, clinicians may pursue a 2-week empiric trial of toxoplasmosis therapy. A repeat scan should be performed at 2 weeks. If the lesion has not diminished in size, biopsy of the lesion should be performed. Since many HIV-infected patients will have detectable titers, a positive Toxoplasma serologic test does not confirm the diagnosis. Conversely, < 3% of patients with toxoplasmosis have negative titers. Therefore, negative Toxoplasma titers in an HIV-infected patient with a space-occupying lesion should be a cause for aggressively pursuing an alternative diagnosis.

2. Central nervous system lymphoma
Primary non-Hodgkin lymphoma is the second most common space-occupying lesion in HIV-infected patients. Symptoms are similar to those with toxoplasmosis. While imaging techniques cannot distinguish these two diseases with certainty, lymphoma more often is solitary. Other less common lesions should be suspected if there is preceding bactere-mia, positive tuberculin test, fungemia, or injection drug use. These include bacterial abscesses, cryptococcomas, tuberculomas, and Nocardia lesions.

Because techniques for stereotactic brain biopsy have improved, this procedure plays an increasing role in diagnosing cerebral lesions. Biopsy should be strongly considered if lesions are solitary or do not respond to toxoplasmosis treatment, especially if they are easily accessible. Diagnosis of lymphoma is important because many patients benefit from treatment (radiation therapy). Although a positive polymerase chain reaction (PCR) assay of cerebrospinal fluid for Epstein–Barr virus DNA, is consistent with a diagnosis of lymphoma, the sensitive and specificity of the test are not high enough to obviate the need for a brain biopsy.

3. HIV-associated dementia
Patients with HIV-associated dementia typically have difficulty with cognitive tasks (eg, memory, attention), exhibit diminished motor function, and have emotional or behavioral problems. Patients may first notice a deterioration in their handwriting. The manifestations of dementia may wax and wane, with persons exhibiting periods of lucidity and confusion over the course of a day. The diagnosis of HIV-associated dementia is one of exclusion based on a brain imaging study and on spinal fluid analysis that excludes other pathogens. Neuropsychiatric testing is helpful in distinguishing patients with dementia from those with depression. Many patients improve with effective antiretroviral treatment. Metabolic abnormalities may also cause changes in mental status: hypoglycemia, hyponatremia, hypoxia, and drug overdose are important considerations in this population. Other less common infectious causes of encephalopathy include progressive multifocal leukoencephalopathy (discussed below), CMV, syphilis, and herpes simplex encephalitis.

4. Cryptococcal meningitis
Cryptococcal meningitis typically presents with fever and headache. Less than 20% of patients have meningismus. Diagnosis is based on a positive latex agglutination test that detects cryptococcal antigen (or "CRAG") or positive culture of spinal fluid for Cryptococcus. Seventy to 90% of patients with cryptococcal meningitis have a positive serum CRAG. Thus, a negative serum CRAG test makes a diagnosis of cryptococcal meningitis unlikely and can be useful in the initial evaluation of a patient with headache, fever, and normal mental status. HIV meningitis, characterized by lymphocytic pleocytosis of the spinal fluid with negative culture, is common early in HIV infection.
5. HIV myelopathy—Spinal cord function may also be impaired in HIV-infected individuals. HIV myelopathy presents with leg weakness and incontinence. Spastic paraparesis and sensory ataxia are seen on neurologic examination. Myelopathy is usually a late manifestation of HIV disease, and most patients will have concomitant HIV encephalopathy. Pathologic evaluation of the spinal cord reveals vacuolation of white matter. Because HIV myelopathy is a diagnosis of exclusion, symptoms suggestive of myelopathy should be evaluated by lumbar puncture to rule out CMV polyradiculopathy (described below) and an MRI or CT scan to exclude epidural lymphoma.

6. Progressive multifocal leukoencephalopathy (PML)—PML is a viral infection of the white matter of the brain seen in patients with very advanced HIV infection. It typically results in focal neurologic deficits such as aphasia, hemiparesis, and cortical blindness. Imaging studies are strongly suggestive of the diagnosis if they show nonenhancing white matter lesions without mass effect. Extensive lesions may be difficult to differentiate from the changes caused by HIV. Several patients have stabilized or improved after the institution of effective ART or cidofovir, or both.

D. Peripheral Nervous System

A. Presentation—Peripheral nervous system syndromes include inflammatory polyneuropathies, sensory neuropathies, and mononeuropathies.

An inflammatory demyelinating polyneuropathy similar to Guillain-Barré syndrome occurs in HIV-infected patients, usually prior to frank immunodeficiency. The syndrome in many cases improves with plasmapheresis, supporting an autoimmune basis of the disease. CMV can cause an ascending polyradiculopathy characterized by lower extremity weakness and a neutrophilic pleocytosis on spinal fluid analysis with a negative bacterial culture. Transverse myelitis can be seen with herpes zoster or CMV.

Peripheral neuropathy is common among HIV-infected persons. Patients typically complain of numbness, tingling, and pain in the lower extremities. Symptoms are disproportionate to findings on gross sensory and motor evaluation. Beyond HIV infection itself, the most common cause is prior ART with stavudine or didanosine. Although not used commonly in Western countries, stavudine is still being used in resource-limited settings through national ART programs. Caution should be used when administering these agents to patients with a history of peripheral neuropathy. Unfortunately, drug-induced neuropathy is not always reversed when the offending agent is discontinued. Patients with advanced disease may also develop peripheral neuropathy even if they have never taken ART. Evaluation should rule out other causes of sensory neuropathy such as alcoholism, thyroid disease, vitamin B₁₂ deficiency, and syphilis.

B. Management—Treatment of peripheral neuropathy is aimed at symptomatic relief. Patients should be initially treated with gabapentin (start at 300 mg at bedtime and increase to 300–900 mg orally three times a day).

E. Rheumatologic and Bone Manifestations

Arthritis, involving single or multiple joints, with or without effusion, has been commonly noted in HIV-infected patients. Involvement of large joints is most common. Although the cause of HIV-related arthritis is unknown, most patients will respond to nonsteroidal anti-inflammatory drugs. Patients with a sizable effusion, especially if the joint is warm or erythematous, should have the joint aspirated, followed by culture of the fluid to rule out suppurative arthritis as well as fungal and mycobacterial disease.

Several rheumatologic syndromes, including reactive arthritis, psoriatic arthritis, sicca syndrome, and systemic lupus erythematosus, have been reported in HIV-infected patients (see Chapter 20). However, it is unclear if the prevalence is greater than in the general population. Cases of avascular necrosis of the femoral heads have been reported sporadically, generally in the setting of advanced disease with long-standing infection and in patients receiving long-term ART. The etiology is not clear but is probably multifactorial in nature.

Osteoporosis and osteopenia appear to be more common in HIV infected patients with chronic infection and perhaps associated with long-term use of ART. Vitamin D deficiency appears to be quite common among HIV-infected populations and monitoring vitamin D levels and replacement therapy for detected deficiency is recommended. Bone scans to determine bone density for patients over the age of 50 is also recommended.

F. Myopathy

Myopathies are infrequent in the era of effective ART but can be related to either HIV-infection or ART, particularly with use of zidovudine (azidothymidine [AZT]). Proximal muscle weakness is typical, and patients may have varying degrees of muscle tenderness. A muscle biopsy can distinguish HIV myopathy from zidovudine myopathy and should be considered in patients for whom continuation of zidovudine is essential.

G. Retinitis

Complaints of visual changes must be evaluated immediately in HIV-infected patients. CMV retinitis, characterized by perivascular hemorrhages and white fluffy exudates, is the most common retinal infection in AIDS patients and can be rapidly progressive. In contrast, cotton wool spots, which are also common in HIV-infected people, are benign, remit spontaneously, and appear as small indistinct white spots without exudation or hemorrhage. This distinction may be difficult at times for the nonspecialist, and patients with visual changes should be seen by an ophthalmologist. Other rare retinal processes include other herpesvirus infections or toxoplasmosis.

H. Oral Lesions

A. Presentation—The presence of oral candidiasis or hairy leukoplakia is significant for several reasons. First, these lesions are highly suggestive of HIV infection in patients who have no other obvious cause of immunodeficiency. Second,
several studies have indicated that patients with candidiasis have a high rate of progression to AIDS even with statistical adjustment for CD4 count.

Hairy leukoplakia is caused by the Epstein-Barr virus. The lesion is not usually troubling to patients and sometimes regresses spontaneously. Hairy leukoplakia is commonly seen as a white lesion on the lateral aspect of the tongue. It may be flat or slightly raised, is usually corrugated, and has vertical parallel lines with fine or thick (“hairy”) projections. Oral candidiasis can be bothersome to patients, many of whom report an unpleasant taste or mouth dryness. The two most common forms of oral candidiasis seen are pseudomembranous (removable white plaques) and erythematous (red friable plaques).

**B. Management**—Treatment is with topical agents such as clotrimazole 10-mg troches (one troche four or five times a day). Patients with candidiasis who do not respond to topical antifungals can be treated with fluconazole (50–100 mg orally once a day for 3–7 days). Angular cheilitis—fissures at the sides of the mouth—is usually due to *Candida* as well and can be treated topically with ketoconazole cream (2%) twice a day.

Gingival disease is common in HIV-infected patients and is thought to be due to an overgrowth of microorganisms. It usually responds to professional dental cleaning and chlorhexidine rinses. A particularly aggressive gingivitis or periodontitis will develop in some HIV-infected patients; these patients should be given antibiotics that cover anaerobic oral flora (eg, metronidazole, 250 mg four times a day for 4 or 5 days) and referred to oral surgeons with experience with these entities.

Aphthous ulcers are painful and may interfere with eating. They can be treated with fluocinonide (0.05% ointment mixed 1:1 with plain Orabase and applied six times a day to the ulcer). For lesions that are difficult to reach, patients should use dexamethasone swishes (0.5 mg in 5 mL elixir three times a day). The pain of the ulcers can be relieved with use of an anesthetic spray (10% lidocaine). Other lesions seen in the mouths of HIV-infected patients include Kaposi sarcoma (usually on the hard palate) and warts.

**I. Gastrointestinal Manifestations**

1. **Candidal esophagitis**—(See also discussion in Chapter 15.) Esophageal candidiasis is a common AIDS complication. In a patient with characteristic symptoms, empiric antifungal treatment is begun with fluconazole (200 mg daily for 10–14 days). Further evaluation to identify other causes of esophagitis (herpes simplex, CMV) is reserved for patients who do not improve with antifungal treatment.

2. **Hepatic disease**—

   **A. Presentation**—Autopsy studies have demonstrated that the liver is a frequent site of infections and neoplasms in HIV-infected patients. However, many of these infections are not clinically symptomatic. Clinicians may note elevations of alkaline phosphatase and aminotransferases on routine chemistry panels. Mycobacterial disease, CMV, hepatitis B virus, hepatitis C virus, and lymphoma cause liver disease and can present with varying degrees of nausea, vomiting, right upper quadrant abdominal pain, and jaundice. Sulfonamides, imidazole drugs, antituberculous medications, pentamidine, clarithromycin, and didanosine have also been associated with hepatitis. HIV-infected patients with chronic hepatitis may have more rapid progression of liver disease because of the concomitant immunodeficiency or hepatotoxicity of ART. Percutaneous liver biopsy may be helpful in diagnosing liver disease, but some common causes of liver disease (eg, *Mycobacterium avium* complex, lymphoma) can be determined by less invasive measures (eg, blood culture, biopsy of a more accessible site).

   **B. Management**—With patients living longer as a result of advances in ART, advanced liver disease and hepatic failure due to chronic active hepatitis B and or C are increasing causes of morbidity and mortality. HIV-infected individuals who are coinfected with hepatitis B, should be treated with antiretroviral regimens that include drugs with activity against both viruses (eg, lamivudine [3TC], emtricitabine [FTC], tenofovir [TDF]). Treatment of HIV-infected persons with hepatitis C with peginterferon and ribavirin has been shown to be efficacious, although less so than in HIV-uninfected persons. HIV-infected persons are also more likely to have difficulty tolerating treatment with peginterferon than uninfected persons. HIV-infected persons with hepatitis C genotype 1 who received telaprevir therapy for 12 weeks had a better response than those who received only peginterferon and ribavirin. Telaprevir is approved in combination with peginterferon and ribavirin for treatment of hepatitis C in HIV-uninfected persons. Patients with advanced fibrosis or cirrhosis due to chronic hepatitis C infection should be considered for treatment with telaprevir, peginterferon, and ribavirin. However, this treatment regimen is difficult for many patients to tolerate, therefore, coinfected patients with less advanced liver disease may benefit from waiting until newer direct-acting agents for hepatitis C treatment become available. Liver transplants have been performed successfully in HIV-infected patients. This strategy is most likely to be successful in persons who have CD4 counts > 100 cells/mL and non-detectable viral loads.

3. **Biliary disease**—Cholecystitis presents with manifestations similar to those seen in immunocompetent hosts but is more likely to be acalculous. Sclerosing cholangitis and papillary stenosis have also been reported in HIV-infected patients. Typically, the syndrome presents with severe nausea, vomiting, and right upper quadrant pain. Liver function tests generally show alkaline phosphatase elevations disproportionate to elevation of the aminotransferases. Although dilated ducts can be seen on ultrasound, the diagnosis is made by endoscopic retrograde cholangiopancreatography, which reveals intraluminal irregularities of the proximal intrahepatic ducts with “pruning” of the terminal ductal branches. Stenosis of the distal common bile duct at the papilla is commonly seen with this syndrome. CMV, *Cryptosporidium*, and microsporidia are thought to play inciting roles in this syndrome.
A. **Presentation**—Enterocolitis is a common problem in HIV-infected individuals. Organisms known to cause enterocolitis include bacteria (*Campylobacter, Salmonella, Shigella*), viruses (CMV, adenovirus), and protozoans (*Cryptosporidium, Entamoeba histolytica, Giardia, Isospora, microsporidia*). HIV itself may cause enterocolitis. Several of the organisms causing enterocolitis in HIV-infected individuals also cause diarrhea in immunocompetent persons. However, HIV-infected patients tend to have more severe and more chronic symptoms, including high fevers and severe abdominal pain that can mimic acute abdominal catastrophes. Bacteremia and concomitant biliary involvement are also more common in enterocolitis in HIV-infected patients. Relapses of enterocolitis following adequate therapy have been reported with both *Salmonella* and *Shigella* infections.

Because of the wide range of agents known to cause enterocolitis, a stool culture and multiple stool examinations for ova and parasites (including modified acid-fast staining for *Cryptosporidium*) should be performed. Those patients who have *Cryptosporidium* in one stool with improvement in symptoms in < 1 month should not be considered to have AIDS, as *Cryptosporidium* is a cause of self-limited diarrhea in HIV-negative persons. More commonly, HIV-infected patients with *Cryptosporidium* infection have persistent enterocolitis with profuse watery diarrhea.

B. **Management**—To date, no consistently effective treatments have been developed for *Cryptosporidium* infection. The most effective treatment of cryptosporidiosis is to improve immune function through the use of effective antiretroviral treatment. The diarrhea can be treated symptomatically with diphenoxylate with atropine (one or two tablets orally three or four times a day). Those who do not respond may be given paregoric with bismuth (5–10 mL orally three or four times a day). Octreotide in escalating doses (starting at 0.05 mg subcutaneously every 8 hours for 48 hours) has been found to ameliorate symptoms in approximately 40% of patients with cryptosporidia or idiopathic HIV-associated diarrhea.

Patients with a negative stool examination and persistent symptoms should be evaluated with colonoscopy and biopsy. Patients whose symptoms last longer than 1 month with no identified cause of diarrhea are considered to have a presumptive diagnosis of AIDS enteropathy. Patients may respond to institution of effective antiretroviral treatment. Upper endoscopy with small bowel biopsy is not recommended as a routine part of the evaluation.

5. **Other disorders**—Two other important gastrointestinal abnormalities in HIV-infected patients are gastropathy and malabsorption. It has been documented that some HIV-infected patients do not produce normal levels of stomach acid and therefore are unable to absorb drugs that require an acid medium. This decreased acid production may explain, in part, the susceptibility of HIV-infected patients to *Campylobacter, Salmonella*, and *Shigella*, all of which are sensitive to acid concentration. There is no evidence that *Helicobacter pylori* is more common in HIV-infected persons.

A malabsorption syndrome occurs commonly in AIDS patients. It can be due to infection of the small bowel with *M. avium complex*, *Cryptosporidium*, or microsporidia.

### J. Endocrinologic Manifestations

Hypogonadism is probably the most common endocrinologic abnormality in HIV-infected men. The adrenal gland is also a commonly afflicted endocrine gland in patients with AIDS. Abnormalities demonstrated on autopsy include infection (especially with CMV and *M. avium* complex), infiltration with Kaposi sarcoma, and injury from hemorrhage and presumed autoimmunity. The prevalence of clinically significant adrenal insufficiency is low. Patients with suggestive symptoms should undergo a cosyntropin stimulation test.

Although frank deficiency of cortisol is rare, an isolated defect in mineralocorticoid metabolism may lead to salt-wasting and hyperkalemia. Such patients should be treated with fludrocortisone (0.1–0.2 mg daily).

AIDS patients appear to have abnormalities of thyroid function tests different from those of patients with other chronic diseases. AIDS patients have been shown to have high levels of triiodothyronine (*T₃*), thyroxine (*T₄*), and thyroid-binding globulin and low levels of reverse triiodothyronine (*rT₃*). The causes and clinical significance of these abnormalities are unknown.

### K. Skin Manifestations

The skin manifestations that commonly develop in HIV-infected patients can be grouped into viral, bacterial, fungal, neoplastic, and nonspecific dermatitides.

1. **Viral dermatitides**—

   A. **Herpes simplex infections**—These infections occur more frequently, tend to be more severe, and are more likely to disseminate in AIDS patients than in immunocompetent persons. Because of the risk of progressive local disease, all herpes simplex attacks should be treated with acyclovir (400 mg orally three times a day until healed, usually 7 days), famciclovir (500 mg orally twice daily until healed), or valacyclovir (500 mg orally twice daily until healed). To avoid the complications of attacks, many clinicians recommend suppressive therapy for HIV-infected patients with a history of recurrent herpes. Options for suppressive therapy include acyclovir (400 mg orally twice daily), famciclovir (250 mg orally twice daily), and valacyclovir (500 mg orally daily). A randomized trial of women infected with both herpes simplex and HIV showed that suppressive therapy with valacyclovir at a dose of 500 mg orally twice daily decreased genital and plasma HIV-1 RNA levels, suggesting the possibility that suppressive treatment may reduce HIV transmission. However, a recent large randomized clinical trial failed to show a reduction in HIV transmission with suppressive acyclovir therapy.
B. **Herpes zoster**—This is a common manifestation of HIV infection. As with herpes simplex infections, patients with zoster should be treated with acyclovir to prevent dissemination (800 mg orally four or five times per day for 7 days). Alternatively, famciclovir (500 mg orally three times a day) or valacyclovir (500 mg three times a day) may be used. Vesicular lesions should be cultured if there is any question about their origin, since herpes simplex responds to much lower doses of acyclovir. Disseminated zoster and cases with ocular involvement should be treated with intravenous (10 mg/kg every 8 hours for 7–10 days) rather than oral acyclovir.

C. **Molluscum contagiosum**—This infection is caused by a pox virus is seen in HIV-infected patients, as in other immunocompromised patients. The characteristic umbilicated fleshy papular lesions have a propensity for spreading widely over the patient’s face and neck and should be treated with topical liquid nitrogen.

2. **Bacterial dermatitides**

A. **Staphylococcal infection**—*Staphylococcus* is the most common bacterial cause of skin disease in HIV-infected patients; it usually presents as **foliculitis, superficial abscesses** (furuncles), or **bullous impetigo**. Because dissemination with sepsis has been reported, attempts should be made to treat these lesions aggressively. Folliculitis is initially treated with topical clindamycin or mupirocin, and patients may benefit from regular washing with an antibacterial soap such as chlorhexidine. Intranasal mupirocin has been used successfully for staphylococcal decolonization in other settings. In HIV-infected patients with recurrent staphylococcal infections, weekly intranasal mupirocin should be considered in addition to topical care and systemic antibiotics. Abscesses often require incision and drainage. Patients may need antistaphylococcal antibiotics as well. Due to high frequency of methicillin-resistant *Staphylococcus aureus* (MRSA) skin infections in HIV-infected populations, lesions should be cultured prior to initiating empiric antistaphylococcal therapy. Although there is limited experience treating MRSA with oral antibiotics, current recommendations for empiric treatment are trimethoprim-sulfamethoxazole (one double-strength tablet orally twice daily) with or without clindamycin (500 mg orally three times daily) or doxycycline (100 mg orally twice daily) with close follow-up.

B. **Bacillary angiomatosis**—This is a well-described entity in HIV-infected patients. It is caused by two closely related organisms: *Bartonella henselae* and *Bartonella quintana*. The epidemiology of these infections suggests zoonotic transmission from fleas of infected domestic cats. The most common manifestation is raised, reddish, highly vascular skin lesions that can mimic the lesions of Kaposi sarcoma. Fever is a common manifestation of this infection; involvement of bone, lymph nodes, and liver has also been reported. The infection responds to doxycycline, 100 mg orally twice daily, or erythromycin, 250 mg orally four times daily. Therapy is continued for at least 14 days, and patients who are seriously ill with visceral involvement may require months of therapy.

3. **Fungal rashes**

A. **Rashes due to dermatophytes and Candida**—The majority of **fungal rashes** affecting AIDS patients are due to dermatophytes and *Candida*. These are particularly common in the inguinal region but may occur anywhere on the body. Fungal rashes generally respond well to topical clotrimazole (1% twice a day) or ketoconazole (2% twice a day).

B. **Seborrheic dermatitis**—This is more common in HIV-infected patients. Scrapings of seborrhea have revealed *Malassezia furfur* (*Pityrosporum ovale*), implying that the seborrhea is caused by this fungus. Consistent with the isolation of this fungus is the clinical finding that seborrhea responds well to topical clotrimazole (1% cream) as well as hydrocortisone (1% cream).

4. **Neoplastic dermatitides**—See Chapter 6 and the Kaposi sarcoma section below.

5. **Non-specific dermatitides**

A. **Xerosis**—This condition presents in HIV-infected patients with severe pruritus. The patient may have no rash, or non-specific excoriations from scratching. Treatment is with emollients (eg, absorption base cream) and antipruritic lotions (eg, camphor 9.5% and menthol 0.5%).

B. **Psoriasis**—Psoriasis can be very severe in HIV-infected patients. Phototherapy and etretinate (0.25–0.75 mg/kg orally in divided doses) may be used for recalcitrant cases in consultation with a dermatologist.

L. **HIV-Related Malignancies**

Four cancers are currently included in the CDC classification of AIDS: Kaposi sarcoma, non-Hodgkin lymphoma, primary lymphoma of the brain, and invasive cervical carcinoma. Epidemiologic studies have shown that between 1973 and 1987 among single men in San Francisco, the risk of Kaposi sarcoma increased more than 3000-fold and the risk of non-Hodgkin lymphoma more than tenfold. The increase in incidence of malignancies is probably a function of impaired cell-mediated immunity.

1. **Kaposi sarcoma**

A. **Presentation**—Lesions may appear anywhere; careful examination of the eyelids, conjunctiva, pinnae, palate, and toe webs is mandatory to locate potentially occult lesions. In light-skinned individuals, Kaposi lesions usually appear as purplish, nonblanching lesions that can be papular or nodular. In dark-skinned individuals, the lesions may appear more brown. In the mouth, lesions are most often palatal papules, though exophytic lesions of the tongue and gingivae may also be seen. Kaposi lesions may be confused with other vascular lesions such as angiomas and pyogenic granulomas. Visceral disease (eg, gastrointestinal, pulmonary) will develop in about 40% of patients with dermatologic Kaposi sarcoma. Kaposi sarcoma lesions can occur shortly after initiating ART, especially in patients starting ART who have advanced immunodeficiency. In this situation, Kaposi sarcoma is likely to be an immune reconstitution reaction (see below).
**B. Management**—Rapidly progressive dermatologic or visceral disease is best treated with systemic chemotherapy. Liposomally encapsulated doxorubicin given intravenously every 3 weeks has a response rate of approximately 70%. α-Interferon (10 million units subcutaneously three times a week) also has activity against Kaposi sarcoma. However, symptoms such as malaise and anorexia limit the utility of this therapy. Patients with milder forms of Kaposi sarcoma do not require specific treatment as the lesions usually improve and can completely resolve with ART. However, it should be noted that the lesions may flare when ART is first initiated—probably as a result of an immune reconstitution process (see Inflammatory reactions below).

**2. Non-Hodgkin lymphoma**—

**A. Presentation**—Non-Hodgkin lymphoma in HIV-infected persons tends to be very aggressive. The malignancies are usually of B cell origin and characterized as diffuse large-cell tumors. Over 70% of the malignancies are extranodal.

**B. Management**—The prognosis of patients with systemic non-Hodgkin lymphoma depends primarily on the degree of immunodeficiency at the time of diagnosis. Patients with high CD4 counts do markedly better than those diagnosed at a late stage of illness. Patients with primary central nervous system lymphoma are treated with radiation. Response to treatment is good, but prior to the availability of HAART, most patients died within a few months after diagnosis due to their underlying disease. Systemic disease is treated with chemotherapy. Common regimens are CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) and modified M-BACOD (methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine, and dexamethasone). Granulocyte colony-stimulating factor (G-CSF; filgrastim) is used to maintain white blood counts with this latter regimen. Intrathecal chemotherapy is administered to prevent or treat meningeal involvement.

**3. Hodgkin disease**—Although Hodgkin disease is not included as part of the CDC definition of AIDS, studies have found that HIV infection is associated with a fivefold increase in the incidence of Hodgkin disease. HIV-infected persons with Hodgkin disease are more likely to have mixed cellularity and lymphocyte depletion subtypes of Hodgkin disease and to seek medical attention at an advanced stage of disease.

**4. Anal dysplasia and squamous cell carcinoma**—

These lesions have been strongly correlated with previous infection by human papillomavirus (HPV) and have been noted in HIV-infected men and women. Although many of the infected MSM report a history of anal warts or have visible warts, a significant percentage have silent papillomavirus infection. Cytologic (using Papanicolaou smears) and papillomavirus DNA studies can easily be performed on specimens obtained by anal swab. Because of the risk of progression from dysplasia to cancer in immunocompromised patients, some experts suggest that annual anal swabs for cytologic examination should be done in all HIV-infected persons. An anal Papanicolaou smear is performed by rotating a moistened Dacron swab about 2 cm into the anal canal. The swab is immediately inserted into a cytology bottle. However, there is no evidence that screening for anal cancer with Papanicolaou smears decreases the incidence of invasive cancer.

HPV also appears to play a causative role in cervical dysplasia and neoplasia. The incidence and clinical course of cervical disease in HIV-infected women are discussed below.

**M. Gynecologic Manifestations**

Vaginal candidiasis, cervical dysplasia and neoplasia, and pelvic inflammatory disease are more common in HIV-infected women than in uninfected women. These manifestations also tend to be more severe when they occur in association with HIV infection. Therefore, HIV-infected women need frequent gynecologic care. Vaginal candidiasis may be treated with topical agents (see Chapter 36). However, HIV-infected women with recurrent or severe vaginal candidiasis may need systemic therapy.

The incidence of cervical dysplasia in HIV-infected women is 40%. Because of this finding, HIV-infected women should have Papanicolaou smears every 6 months (as opposed to the Agency for Healthcare Research and Quality [AHRQ] Guideline recommendation for every 12 months). Some clinicians recommend routine colposcopy or cervicography because cervical intraepithelial neoplasia has occurred in women with negative Papanicolaou smears. Cone biopsy is indicated in cases of serious cervical dysplasia. For 1 year following treatment of an abnormal Papanicolaou smear, women should have repeat smears every 3 to 4 months.

Cervical neoplasia appears to be more aggressive among HIV-infected women. Most HIV-infected women with cervical cancer die of that disease rather than of AIDS. Because of its frequency and severity, cervical neoplasia was added to the CDC definition of AIDS in 1993.

While pelvic inflammatory disease appears to be more common in HIV-infected women, the bacteriology of this condition appears to be the same as among HIV-uninfected women. At present, HIV-infected women with pelvic inflammatory disease should be treated with the same regimens as uninfected women (see Chapter 18). However, inpatient therapy is generally recommended.

**N. Coronary Artery Disease**

HIV-infected persons are at higher risk for coronary artery disease than age- and sex-matched controls. Part of this increase in coronary artery disease is due to changes in lipids caused by antiretroviral agents (see Treatment section on Antiretroviral Therapy below), especially stavudine and several of the PIs. However, some of the risk appears to be due to HIV infection, independent of its therapy. It is important that clinicians pay close attention to this issue because the first presentation of coronary artery disease in HIV-infected persons may be sudden death. HIV-infected patients with symptoms of coronary artery disease such as chest pain or dyspnea should be rapidly evaluated. Clinicians should aggressively treat conditions that result
in increased risk of heart disease, especially smoking, hypertension, hyperlipidemia, obesity, diabetes mellitus, and sedentary lifestyle.

O. Inflammatory Reactions (Immune Reconstitution Syndromes)

With initiation of HAART, some patients experience inflammatory reactions that appear to be associated with immune reconstitution as indicated by a rapid increase in CD4 count. These inflammatory reactions may present with generalized signs of fevers, sweats, and malaise with or without more localized manifestations that usually represent unusual presentations of opportunistic infections. For example, vitreitis has developed in patients with CMV retinitis after they have been treated with HAART.

*M. avium* can present as focal even suppurative lymphadenitis or granulomatous masses in patients receiving HAART. Tuberculosis may paradoxically worsen with new or evolving pulmonary infiltrates and lymphadenopathy. PML and cryptococcal menigitis may also be atypical. Clinicians should be alert to these syndromes, which are most often seen in patients who have initiated ART in the setting of advanced disease and who show rapid increases in CD4 counts with treatment. The diagnosis of IRIS is one of exclusion and can be made only after recurrence or new opportunistic infection has been ruled out as the cause of the clinical deterioration. Management of IRIS is conservative and supportive with use of corticosteroids only for severe reactions. Most authorities recommend that ART be continued unless the reaction is life-threatening.

▶ Prevention

A. Primary Prevention

Until vaccination is a reality, prevention of HIV infection will depend on effective precautions regarding sexual practices and injection drug use, use of perinatal HIV prophylaxis, screening of blood products, and infection control practices in the health care setting. Primary care clinicians should routinely obtain a sexual history and perform risk factor assessment of their patients. Because approximately one-fifth of the HIV-infected persons in the United States do not know they are infected, the CDC recommends all adults be tested for HIV as a routine part of medical care. Clinicians should review the risk factors for HIV infection with the patient and discuss safer sex and safer needle use as well as the meaning of a positive test. Although the CDC recommends “opt-out” testing in medical settings, some states require specific written consent. For persons whose test results are positive, referrals for partner-notification services, social services, mental health services, and HIV-prevention services should be provided. Prevention interventions focused on the importance of HIV-infected persons not putting others at risk have been successful. For patients whose test results are negative, clinicians should review safer sex and needle use practices, including counseling not to exchange bodily fluids unless they are in a long-term mutually monogamous relationship with someone who has tested HIV antibody-negative and has not engaged in unsafe sex, injection drug use, or other HIV risk behaviors for at least 6 months prior to or at any time since the negative test.

Only latex condoms should be used, along with a water-soluble lubricant. Although nonoxynol-9, a spermicide, kills HIV, it is contraindicated because in some patients it may cause genital ulcers that could facilitate HIV transmission. Patients should be counseled that condoms are not 100% effective. They should be made familiar with the use of condoms, including, specifically, the advice that condoms must be used every time, that space should be left at the tip of the condom as a receptacle for semen, that intercourse with a condom should not be attempted if the penis is only partially erect, that men should hold on to the base of the condom when withdrawing the penis to prevent slippage, and that condoms should not be reused. Although anal intercourse remains the sexual practice at highest risk for transmitting HIV, seroconversions have been documented with vaginal and oral intercourse as well. Therefore, condoms should be used when engaging in these activities. Women as well as men should understand how to use condoms so as to be sure that their partners are using them correctly. Several recent randomized trials in Africa demonstrated that male circumcision significantly reduced HIV incidence in men, but there are a number of barriers to performing widespread circumcisions among men in Africa.

Two major studies have demonstrated the proof of concept that HIV transmission can be reduced by drugs that are used to treat HIV infection. In a study from South Africa, women who used a tenofovir-containing vaginal gel reduced their risk of HIV infection by 39% and those who followed the recommended application schedule (use before and after intercourse) had a more than 50% reduction in risk of infection. In a randomized placebo-controlled study of MSM across several different countries, researchers showed that risk of HIV transmission was reduced by 44% in those men receiving daily tenofovir/emtricitabine fixed-dose combination; in those who were over 90% adherent, the risk was reduced more 70%. Although transmission was not universally prevented in either of these studies, they demonstrate that “biological methods” could serve as a useful adjunct to current behavioral approaches in preventing HIV transmission.

In addition, having persons with HIV take effective ART appears to reduce the chance that they can transmit HIV to their partners. An international study showed that among serodiscordant couples, early ART almost completely eliminated the risk of HIV transmission to the uninfected partner. Although HIV-negative persons in stable long-term partnerships with HIV-infected persons represent only one group of at risk persons, theoretically increasing the use of ART among the population of HIV-infected persons could decrease community wide transmission of HIV.

Persons using injection drugs should be cautioned never to exchange needles or other drug paraphernalia. When sterile needles are not available, bleach does appear to inactivate HIV and should be used to clean needles.
Current efforts to screen blood and blood products have lowered the risk of HIV transmission with transfusion of a unit of blood to 1:1,000,000.

In health care settings, universal body fluid precautions should be used, including use of gloves when handling body fluids and the addition of gown, mask, and goggles for procedures that may result in splash or droplet spread, and use of specially designed needles with sheath devices to decrease the risk of needle sticks. Because transmission of tuberculosis may occur in health care settings, all patients with cough should be encouraged to wear masks. Hospitalized HIV-infected patients with cough should be placed in respiratory isolation until tuberculosis can be excluded by chest radiograph and sputum smear examination.

Primate model data have suggested that development of a protective vaccine may be possible, but clinical trials in humans have been disappointing. Only one vaccine trial has shown any degree of efficacy. In this randomized, double-blind, placebo-controlled trial, a recombinant canarypox vector vaccine plus two booster injections of a recombinant gp120 vaccine was moderately efficacious (26–31%) in reducing the risk of HIV among a primarily heterosexual population in Thailand. Current vaccine development efforts are aimed at identifying broadly neutralizing antibodies to the highly conserved regions of the HIV envelope.

B. Secondary Prevention

In the era prior to the development of highly effective antiretroviral treatment, cohort studies of individuals with documented dates of seroconversion demonstrate that AIDS develops within 10 years in approximately 50% of untreated seropositive persons. With currently available treatment, progression of disease has been markedly decreased. In addition to antiretroviral treatment, prophylactic regimens can prevent opportunistic infections and improve survival. Prophylaxis and early intervention prevent several infectious diseases, including tuberculosis and syphilis, which are transmissible to others. Recommendations for screening tests, vaccinations, and prophylaxis are listed in Table 31–3.

1. **Tuberculosis**—Because of the increased occurrence of tuberculosis among HIV-infected patients, all such individuals should undergo PPD testing. Although anergy is common among AIDS patients, the likelihood of a false-negative result is much lower when the test is done early in infection. Those with positive tests (defined for HIV-infected patients as > 5 mm of induration) need a chest radiograph. Patients with an infiltrate in any location, especially if accompanied by mediastinal adenopathy, should have sputum sent for acid-fast staining. Patients with a positive PPD but negative evaluations for active disease should receive isoniazid (300 mg orally daily) with pyridoxine (50 mg orally daily) for 9 months to a year. A blood test (QuantiFERON Gold test) can also be used to assess prior tuberculosis exposure. Blood samples are mixed with synthetic antigens representing *M tuberculosis*. Patients infected with *M tuberculosis* produce interferon-gamma in response to contact with the antigens. Unlike the PPD, the patient does not have to return for a second visit. The test is less likely to result in false-positive results than a PPD. Unfortunately, HIV-infected persons may not produce sufficient interferon-gamma, in which case the test may be falsely negative.

2. **Syphilis**—Because of recent increases in the number of cases of syphilis among MSM, including those who are HIV infected, all such men should be screened for syphilis by rapid plasma reagin (RPR) or Venereal Disease Research Laboratories (VDRL) test every 6 months. Increases of syphilis cases among HIV-infected persons are of particular concern because these individuals are at increased risk for reactivation of syphilis and progression to tertiary syphilis despite standard treatment. Because the only widely available tests for syphilis are serologic and because HIV-infected individuals are known to have
disordered antibody production, there is concern about the interpretation of these titers. This concern has been fueled by a report of an HIV-infected patient with secondary syphilis and negative syphilis serologic testing. Furthermore, HIV-infected individuals may lose fluorescent treponemal antibody absorption (FTA-ABS) reactivity after treatment for syphilis, particularly if they have low CD4 counts. Thus, in this population, a nonreactive treponemal antibody absorption (FTA-ABS) reactivity after treatment for syphilis, particularly if they have low CD4 counts—drink bottled water instead of tap water to prevent cryptosporidiosis infection.

Because of the emotional impact of HIV infection and subsequent illness, many patients will benefit from supportive counseling.

C. HIV Risk for Health Care Professionals

Epidemiologic studies show that needle sticks occur commonly among health care professionals, especially among surgeons performing invasive procedures, inexperienced hospital house staff, and medical students. Efforts to reduce needle sticks should focus on avoiding recapping needles and use of safety needles whenever doing invasive procedures under controlled circumstances. The risk of HIV transmission from a needle stick with blood from an HIV-infected patient is about 1:300. The risk is higher with deep punctures, large inocula, and source patients with high viral loads. The risk from mucous membrane contact is too low to quantitate.

Health care professionals who sustain needle sticks should be counseled and offered HIV testing as soon as possible. HIV testing is done to establish a negative baseline for worker’s compensation claims in case there is a subsequent conversion. Follow-up testing is usually performed at 6 weeks, 3 months, and 6 months.

A case-control study by the CDC indicates that administration of zidovudine following a needle stick decreases the rate of HIV seroconversion by 79%. Therefore, providers should be offered therapy with Combivir (zidovudine 300 mg plus lamivudine 150 mg orally twice daily). Therapy should be started as soon as possible after exposure and continued for 4 weeks. Providers who have exposures to persons who are likely to have antiretroviral drug resistance (eg, persons receiving therapy who have detectable viral loads) should have their therapy individualized, using at least two drugs to which the source is unlikely to be resistant. Some clinicians recommend triple combination regimens, including a PI for all occupational exposures, because of uncertainty about drug resistance. Others save these more aggressive regimens for the higher-risk exposures listed above. Because reports have noted hepatitis toxicity due to nevirapine in this setting, this agent should be avoided. Unfortunately, there have been documented cases of seroconversion following potential parenteral exposure to HIV despite prompt use of zidovudine.
prophylaxis. Counseling of the provider should include "safer sex" guidelines.

D. Postexposure Prophylaxis for Sexual and Drug Use Exposures to HIV

Following publication of a case-control study indicating that ART decreased the odds of seroconversion among health care workers who had occupational exposure, some experts have recommended offering ART following potential exposure to HIV through sexual activity or drug use. Although there are no efficacy data to support this practice, there are similarities between the immune response following transcutaneous and transmucosal exposures. The goal of postexposure prophylaxis is to reduce or prevent local viral replication prior to dissemination such that the infection can be aborted. The choice of antiretroviral agents and the duration of treatment are the same as those for exposures that occur through the occupational route (see above). In contrast to those with occupational exposures, some individuals may present very late after exposure. Because the likelihood of success declines with length of time from HIV exposure, it is not recommended that treatment be offered after 72 hours. In addition, because the psychosocial issues involved with postexposure prophylaxis for sexual and drug use exposures are complex, it should be offered only in the context of prevention counseling. Counseling should focus on how to prevent future exposures. Clinicians needing more information on postexposure prophylaxis for occupational or nonoccupational exposures should contact the National Clinician's Post-exposure Hotline (1-888-448-4911; http://www.nccc.ucsf.edu/about_nccc/pepline/).

E. Preventing Perinatal Transmission of HIV

A multicenter trial showed that when zidovudine is administered to women during pregnancy, labor, and delivery and to their newborns, the rate of HIV transmission is decreased by two-thirds. An observational trial demonstrated that zidovudine treatment is almost as effective when begun during labor or when administered only to the infant, as long as treatment is begun within 48 hours after birth. Nonetheless, treatment begun by at least the second trimester is still recommended. Many women are currently being offered combination antiretroviral treatment to further lower the risk of transmission. The availability of treatment makes it essential that all women who are pregnant or considering pregnancy be offered HIV counseling and testing. Many obstetricians recommend combination antiretroviral treatment, especially if zidovudine resistance is suspected. HIV-infected women receiving ART in whom pregnancy is recognized during the first trimester should be counseled about the benefits and potential risks to the fetus of treatment during the first trimester. Because healthy mothers make healthy babies, continuation of therapy should be strongly considered. Because about half of fetal infections in non-breast-feeding women occur shortly before or during the birth process, ART should be administered whenever a woman initiates perinatal care even if she did not begin therapy in the second trimester. Breast-feeding is thought to increase the rate of transmission by 10–20% and should be avoided.

### Treatment

Treatment for HIV infection can be broadly divided into the following categories: (1) prophylaxis for opportunistic infections, malignancies, and other complications of HIV infection; (2) treatment of opportunistic infections, malignancies, and other complications of HIV infection; and (3) treatment of the HIV infection itself with combination ART.

Treatment regimens for HIV infection are constantly changing. Clinicians may obtain up-to-date information on new and experimental treatments by calling the AIDS Clinical Trials Information Service (ACTIS), 800-TRIALS-A (English and Spanish), and the National AIDS Hot Line, 800-342-AIDS (English), 800-344-SIDA (Spanish), and 800-AIDS-TTY (hearing-impaired).

A. Prophylactic Treatment of Complications of HIV Infection

In general, decisions about prophylaxis of opportunistic infections are based on the CD4 count, other evidence of severe immunosuppression (eg, oral candidiasis), and a history of having had the infection in the past. In the era prior to HAART, patients who started taking prophylactic regimens were maintained on them indefinitely. However, studies have shown that in patients with robust improvements in immune function—as measured by increases in CD4 counts above the levels that are used to initiate treatment—prophylactic regimens can safely be discontinued.
Because individuals with advanced HIV infection are susceptible to a number of opportunistic pathogens, the use of agents with activity against more than one pathogen is preferable. It has been shown, for example, that trimethoprim-sulfamethoxazole confers some protection against toxoplasmosis in individuals receiving this drug for Pneumocystis prophylaxis.

1. Prophylaxis against Pneumocystis pneumonia—Patients with CD4 counts below 200 cells/mcL, a CD4 lymphocyte percentage below 14%, or weight loss or oral candidiasis should be offered primary prophylaxis for Pneumocystis pneumonia. Patients with a history of Pneumocystis pneumonia should receive secondary prophylaxis until they have had a durable virologic response to HAART for at least 3–6 months and maintain a CD4 count of >250 cells/mcL. Regimens for Pneumocystis prophylaxis are given in Table 31–4.

2. Prophylaxis against M avium complex infection—Patients whose CD4 counts fall to below 75–100 cells/mcL should be given prophylaxis against M avium complex infection. Clarithromycin (500 mg orally twice daily) and azithromycin (1200 mg orally weekly) have both been shown to decrease the incidence of disseminated M avium complex infection by approximately 75%, with a low rate of breakthrough of resistant disease. The azithromycin regimen is generally preferred based on high compliance and low cost. Adding rifabutin increases the toxicity of the regimen but does not significantly increase its efficacy and is therefore not recommended. The azithromycin regimen is generally preferred based on 75%, with a low rate of breakthrough of resistant disease. Patients whose CD4 counts fall to below 75–100 cells/mcL should be given prophylaxis against M avium complex infection. Clarithromycin (500 mg orally twice daily) and azithromycin (1200 mg orally weekly) have both been shown to decrease the incidence of disseminated M avium complex infection by approximately 75%, with a low rate of breakthrough of resistant disease. The azithromycin regimen is generally preferred based on high compliance and low cost. Adding rifabutin increases the toxicity of the regimen but does not significantly increase its efficacy and is therefore not recommended. The azithromycin regimen is generally preferred based on high compliance and low cost. Adding rifabutin increases the toxicity of the regimen but does not significantly increase its efficacy and is therefore not recommended.

3. Prophylaxis against M tuberculosis infection—Isoniazid, 300 mg orally daily, plus pyridoxine, 50 mg orally daily, for 9–12 months should be given to all HIV-infected patients with positive PPD reactions (defined as >5 mm of induration for HIV-infected patients).

4. Prophylaxis against toxoplasmosis—Toxoplasmosis prophylaxis is desirable in patients with a positive IgG toxoplasma serology and CD4 counts below 100 cells/mcL. Trimethoprim-sulfamethoxazole (one double-strength tablet daily) offers good protection against toxoplasmosis, as does a combination of pyrimethamine, 25 mg orally once a week, plus dapsone, 50 mg orally daily, plus leucovorin, 25 mg orally once a week. A glucose-6-phosphate dehydrogenase (G6PD) level should be checked prior to dapsone therapy, and a methemoglobin level should be checked at 1 month.

5. Prophylaxis against CMV infection—Oral ganciclovir (1000 mg three times daily with food) is approved for CMV prophylaxis among HIV-infected persons with advanced disease (eg, CD4 counts below 50 cells/mcL). However, because the drug causes neutropenia, it is not widely used. Clinicians should consider performing serum CMV IgG antibody testing prior to starting ganciclovir. Persons who are CMV IgG-negative are not at risk for development of CMV disease, although it is important that such patients receive only CMV-negative blood if they require transfusion. Because over 99% of MSM are positive for CMV IgG, it is appropriate to reserve such testing for heterosexuals with HIV.

6. Prophylaxis against cryptococcosis, candidiasis, and endemic fungal diseases—One trial showed a decreased incidence of cryptococcal disease with prophylaxis using fluconazole, 200 mg orally daily, but the treated group had no benefit in terms of mortality. Fluconazole (200 mg orally once a week) was found to prevent oral and vaginal candidiasis in women with CD4 counts below 300 cells/mcL. In areas of the world where histoplasmosis and coccidiodomycosis are endemic and are frequent complications of HIV infection, prophylactic use of fluconazole or itraconazole may prove to be useful strategies. However, the problem of identifying individuals at highest risk makes appropriate targeting of prophylaxis difficult.

B. Treatment of Complications of HIV Infection

Treatment of common AIDS-related complications is detailed above and in Table 31–5. In the era prior to the use

Valacyclovir, 500 mg orally twice daily until healed. Foscarnet, 40 mg/kg intravenously every 8 hours, for acyclovir-resistant cases. (Adjust for changes in kidney function.)</td>
<td>Resistant herpes simplex with chronic therapy. Nausea. Nausea. See above.</td>
</tr>
</tbody>
</table>

(continued)
Well-established alternative regimens now also exist for most AIDS-related opportunistic infections: amphotericin B or fluconazole for cryptococcal meningitis; ganciclovir, cidofovir, or foscarnet for CMV infection; and sulfadiazine or clindamycin with pyrimethamine for toxoplasmosis.

Adjunctive Treatments—Although conceptually it would seem that corticosteroids should be avoided in HIV-infected patients, corticosteroid therapy has been shown to improve the course of patients with moderate to severe Pneumocystis jiroveci pneumonia (oxygen saturation < 90%, \( P_{O_2} < 65 \text{ mm Hg} \)) when administered within 72 hours after diagnosis. The mechanism of action is presumed to be a decrease in alveolar inflammation.

Corticosteroids have also been used to treat immune reconstitution and inflammatory syndromes (IRIS) that can sometimes complicate the early treatment course when ART is initiated in patients with advanced AIDS (see section Inflammatory reactions [immune reconstitution syndromes]).

Epoetin alfa (erythropoietin) is approved for use in HIV-infected patients with anemia, including those with anemia secondary to zidovudine use. It has been shown to decrease the need for blood transfusions. The drug is expensive, and
therefore an erythropoietin level < 500 mU/mL should be demonstrated before starting therapy. The starting dose of epoetin alfa is 8000 units subcutaneously three times a week. The target hematocrit is 35–40%. The dose may be increased by 12,000 units every 4–6 weeks as needed to a maximum dose of 48,000 units per week. Hypertension is the most common side effect.

Human G-CSF (filgrastim) and granulocyte-macrophage colony-stimulating factor (GM-CSF [sargramostim]) have been shown to increase the neutrophil counts of HIV-infected patients. Because of the high cost of this therapy, the dosage should be closely monitored and minimized, aiming for a neutrophil count of 1000/mcL. When the drug is used for indications other than cytotoxic chemotherapy, one or two doses at 5 mcg/kg per week are usually sufficient.

C. Antiretroviral Therapy

The availability of agents that in combination suppress HIV replication (Table 31–6) has had a profound impact on the natural history of HIV infection. Indeed, with the advent of antiretroviral treatment, the life expectancy of HIV-infected persons approaches that of uninfected persons when treatment is initiated early in the course of the disease.

The greater potency and the improved side effect profile have led to recommendations to start treatment earlier in the course of HIV disease. Treatment should be initiated for all symptomatic patients, and for asymptomatic persons who (1) have CD4 cell counts below 500 cells/mcL, (2) have rapidly dropping CD4 counts (> 100 cells/mcL/yr) or very high viral loads (> 100,000/mcL), (3) have active infection with hepatitis B or C (rapid HIV replication is thought to hasten progression of hepatitis B and C), (4) have risk factors for cardiac disease (ongoing HIV replication may increase the risk of cardiac disease), (5) have HIV-related renal impairment, (6) pregnancy, or (7) have risk factors for non–AIDS-related cancers (rapid HIV replication may increase such cancers). Current guidelines suggest that patients who have none of the above conditions but are at high risk for transmitting HIV to another person should be considered for ART. However, for patients with difficulty adhering to therapy, deferring ART until the patient is willing to commit to therapy may be a better strategy. In addition, because 5–20% of patients in developed countries who are treatment-naive have a virus that is resistant to some drugs, resistance testing is recommended for all patients prior to initiating ART.

Once a decision to initiate therapy has been made, several important principles should guide therapy. First, because drug resistance to antiretroviral agents develops in HIV-infected patients, a primary goal of therapy should be complete suppression of viral replication as measured by the serum viral load. Therapy that achieves a plasma viral load of < 40 or < 50 copies/mL (depending on the test used) has been shown to provide a durable response to the therapy. To achieve this and maintain virologic control over time, combination therapy with at least 3 drugs from at least two different classes is necessary, and partially suppressive combinations such as dual nucleoside therapy should be avoided. Similarly, if toxicity develops, it is preferable to either interrupt the entire regimen or change the offending drug rather than reduce individual doses.

Two randomized trials compared early initiation of ART (within 2 weeks of starting treatment for an opportunistic infection or tuberculosis) with ART that was deferred until after treatment of the opportunistic infection was completed (6 weeks after its start); results demonstrated that early initiation reduced death or AIDS progression by 50%. The reduced progression rates were related to more rapid improvements in CD4 counts in patients with advanced immunodeficiency. Furthermore, IRIS and other adverse events were no more frequent in the early ART arm. Based on these results, most treatment guidelines recommend that ART be initiated as early as is clinically feasible for patients with an acute AIDS-related opportunistic infection. For hospitalized patients, this recommendation requires close coordination between inpatient and outpatient physicians to ensure that treatment is continued once patients are discharged.

The current standard is to use at least three agents simultaneously from at least two different classes. Because the number of drugs is finite, it is important to avoid drug resistance, which occurs when patients take medications in the setting of ongoing viral replication. Therefore, the best method for avoiding resistance is for the patient to be compliant with an efficacious regimen. Adherence can be promoted through the use of simple regimens (one pill a day combination regimens, and for those patients with more complicated regimens, medication boxes with compartments [eg, Medisets]). Many patients benefit from adherence counseling and some need daily supervision of therapy. Given these options treatment should not be withheld solely on the basis of a patient’s circumstances (eg, active drug use or housing status) alone. Often, a trial intervention such as offering _Pneumocystis_ pneumonia prophylaxis may be helpful in determining the likelihood of adherence to a more complex antiretroviral regimen.

Monitoring of ART has two goals. Laboratory evaluation for toxicity depends on the specific drugs in the combination but generally should be done approximately every 3-4 months once a patient is on a stable regimen. Patients who are intolerant of their initial regimen (eg, patients who cannot tolerate the neurologic side effects of efavirenz) should be changed to an alternative drug or regimen. The second aspect of monitoring is to regularly measure objective markers of efficacy. The CD4 cell count and HIV viral load should be repeated 1–2 months after the initiation or change of antiretroviral regimen and every 4-6 months thereafter in clinically stable patients (those with higher CD4 counts can have testing every 6 months). In a patient who is adherent to an effective regimen, viral loads should be undetectable within 12–24 weeks. For patients in whom viral loads are not suppressed or who have viral rebound after suppression, the major question facing the clinician is whether the patient is nonadherent or has resistance to the regimen, or both. The issue is complicated because many patients report being more compliant than they really are, not because they wish to be untruthful but because they wish to tell the clinician what

he or she wants to hear. Patients who are having trouble adhering to their treatment should receive counseling on how to better comply to their treatment. In patients who are adherent or who have missed enough doses to make resistance possible, resistance testing should be performed. Based on the results of resistance testing, and assessment of the patient’s ability to comply with complicated regimens or to tolerate predictable side effects, the clinician should prescribe a combination of three medications to which there is no or only minimal resistance. Some patients whose counts rise dramatically on ART and who are fully suppressed (ie, plasma viral load < 50 copies/mL) may be successfully transitioned from a high potency regimen to a lower potency regimen with fewer side effects; however, this “induction-maintenance” strategy is still being evaluated in clinical trials. Stopping therapy in patients with

1Standard monitoring is complete blood count (CBC) and differential, serum aminotransferases every 3–4 months, and cholesterol (total, LDL, HDL), and triglycerides 6 months after starting ART and annually among those over age 40 years.

Average wholesale price (AWP, for AB-rated generic when available) for quantity listed. Source: Red Book Online, 2012, Thomson Reuters (Healthcare Inc.). AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions.
high CD4 counts will generally result in patients reverting to their pretreatment nadir CD4 count in a matter of months and is therefore not recommended.

Although the ideal combination of drugs has not yet been defined for all possible clinical situations, possible choices can be better understood after a review of the available agents. These drugs can be grouped into five major categories: nucleoside and nucleotide reverse transcriptase inhibitors (NRTI); PI; nonnucleoside reverse transcriptase inhibitors (NNRTI); entry inhibitors, which include a fusion inhibitor and CCR5 antagonists; and integrase inhibitors. Once ART has been initiated in a patient, it is not advisable to stop the therapy unless there is a compelling reason (eg, toxicity, poor adherence, etc). So-called “drug holidays” or “structured treatment interruptions” have been shown to increase risk of AIDS-related complications, increase CD4 declines, and increase morbidity from non–AIDS-related complications (eg, myocardial infarctions and liver failure) and are not recommended.

1. **Nucleoside and nucleotide reverse transcriptase inhibitors**—There are currently seven nucleoside or nucleotide agents approved for use. The choice of which agent to use depends primarily on the patient’s prior treatment experience, results of resistance testing, drug side effects, other underlying conditions, and convenience of formulation. However, most clinicians use fixed-dose combinations of other tenofovir/emtricitabine (TDF/FTC) or abacavir/lamivudine (ABC/3TC), both of which can be given once a day. Zidovudine/lamivudine (AZT/3TC) is usually reserved for second- or third-line regimens because of toxicity and dosing schedule. Recent studies have raised some concerns about the efficacy of ABC/3TC in patients with high viral loads (eg, >100,000 copies/mL) as well as concerns about increase risks of myocardial infarction with abacavir. Therefore, TDF/FTC is the preferred fixed-dose combination as part of initial treatment regimens.

Of the available agents, zidovudine is the most likely to cause anemia. Zidovudine and didanosine are the most likely to cause neutropenia. Stavudine is the most likely to cause lipatrophy (loss of fat in the face, extremities, and buttocks) followed by zidovudine. Zalcitabine and didanosine are the most likely to cause peripheral neuropathy. Lamivudine, emtricitabine, and tenofovir have activity against hepatitis B. Didanosine, lamivudine, emtricitabine, and tenofovir can be administered daily. Information specific to each drug is given below, and recommendations on how to combine them appear in the Constructing regimens section below.

A. **Zidovudine**—Zidovudine was the first approved anti-HIV infection and remains an important agent. It is administered at a dose of 300 mg orally twice daily. A combination of zidovudine 300 mg and lamivudine 150 mg (Combivir) allows more convenient dosing of medication for individuals taking both of these agents. Side effects seen with zidovudine are listed in Table 31–6. Approximately 40% of patients experience subjective side effects that usually remit within 6 weeks. The common dose-limiting side effects are anemia and neutropenia, which require ongoing laboratory monitoring. Long-term use has been associated with lipatrophy.

B. **Didanosine**—The most convenient formulation of didanosine (ddI) is the enteric-coated capsule. For adults weighing at least 60 kg, the dose is one 400-mg enteric-coated capsule orally daily; for those 30–59 kg, the dose is one 250-mg enteric-coated capsule orally daily. Didanosine should be taken on an empty stomach.

Didanosine has been associated with pancreatitis. The incidence of pancreatitis with didanosine is 5–10%—of fatal pancreatitis, <0.4%. Patients with a history of pancreatitis, as well as those taking other medications associated with pancreatitis (including trimethoprim-sulfamethoxazole and intravenous pentamidine) are at higher risk for this complication. Other common side effects with didanosine include a dose-related, reversible, painful peripheral neuropathy, which occurs in about 15% of patients, and dry mouth. Fulminant hepatic failure and electrolyte abnormalities, including hypokalemia, hypocalcemia, and hypomagnesemia, have been reported in patients taking didanosine. Because of the side-effect profile, didanosine is rarely used today.

C. **Stavudine**—Stavudine (d4T) has shown good activity as an antiretroviral drug. The dose is 40 mg orally twice daily for individuals weighing 60 kg or more. However, because of its side effects including lipatrophy, lipodystrophy (see below), peripheral neuropathy and, rarely, lactic acidosis and hepatitis, this drug should no longer be used except when there is no alternative. Patients taking stavudine should be routinely changed to abacavir or tenofovir, both of which are less likely to cause lipatrophy.

D. **Lamivudine**—Lamivudine (3TC) is a safe and well-tolerated agent. The dosage is 150 mg orally twice daily or 300 mg orally once a day. The dose should be reduced with chronic kidney disease. There are no significant side effects with lamivudine, and it has activity also against hepatitis B.

E. **Emtricitabine**—Emtricitabine is a nucleoside analog that is dosed at 200 mg orally. It was developed primarily as a once-daily alternative to lamivudine. However, lamivudine can be dosed daily, eliminating the special indication for emtricitabine. As is true of lamivudine, emtricitabine has activity against hepatitis B and its dosage should be reduced in patients with chronic kidney disease.

F. **Abacavir**—A daily dose of 300 mg orally twice daily results in potent antiretroviral activity. Prior to initiation of abacavir, patients should undergo testing for HLA typing. Those with the B*5701 allele should not be treated with abacavir because the likelihood of a hypersensitivity reaction developing is high; the reaction is characterized by a flu-like syndrome with rash and fever that worsens with successive doses. Unfortunately, the absence of this allele does not guarantee that the patient will avoid the hypersensitivity reaction. Individuals in whom the hypersensitivity reaction develops should not be rechallenged with this agent because subsequent hypersensitivity reactions can be fatal. Abacavir has also been shown to be associated with an increased risk of myocardial infarction in some cohort studies. This increased risk is generally seen in patients who have underlying risks of cardiovascular disease. Consequently, abacavir should be avoided in such
lipodystrophy. Although changes are referred to as lipodystrophy. Although it is not as efficacious as combining two nucleoside/nucleotide analogs with a PI/ritonavir or an NNRTI; its use as a sole regimen should be reserved only for patients who cannot tolerate a more complicated regimen. Abacavir is also available as a fixed dose combination pill with lamivudine for use as a once daily pill (Epzicom).

G. Zalcitabine—Zalcitabine (ddC) was one of the least effective antiretroviral agents and is no longer being manufactured.

H. Tenofovir—Tenofovir is the only licensed nucleotide analog. It is given as a single daily oral dose of 300 mg and is generally well tolerated. Tenofovir is available in a fixed dose combination pill with emtricitabine (Truvada) for daily dosing and is the only recommended fixed-dose combination for initial regimens. A once-a-day single fixed-dose combination pill that contains efavirenz, emtricitabine, and tenofovir (Atripla) is also available. Tenofovir is active against hepatitis B, including isolates that have resistance to lamivudine.

2. Protease inhibitors—Ten PIs—indinavir, nelfinavir, ritonavir, saquinavir, amprenavir, fosamprenavir, lopinavir (in combination with ritonavir), atazanavir, darunavir, and tipranavir are available. PIs have been shown to potently suppress HIV replication and are administered as part of a combination regimen.

All the PIs—t0 differing degrees—are metabolized by the cytochrome P450 system, and each can inhibit and induce various P450 isoenzymes. Therefore, drug interactions are common and difficult to predict. Clinicians should consult the product inserts before prescribing PIs with other medications. Drugs such as rifampin that are known to induce the P450 system should be avoided.

The fact that the PIs are dependent on metabolism through the cytochrome P450 system has led to the use of ritonavir to boost the drug levels of saquinavir, lopinavir, indinavir, atazanavir, tipranavir, darunavir and amprenavir, allowing use of lower doses and simpler dosing schedules of these PIs. In fact, current guidelines recommend that all PI-containing regimens use ritonavir boosting if possible. The only PIs that can be safely used without ritonavir boosting are nelfinavir and atazanavir.

When choosing which PI to use, prior patient experience, resistance patterns, side effects, and ease of administration are the major considerations. The first three PIs to be developed—indinavir, saquinavir, and ritonavir (as single agents)—are now rarely used because of the superiority of the second generation of PIs. Amprenavir has been almost entirely replaced by its prodrug, fosamprenavir. Unfortunately, all PIs, with the exception of unboosted atazanavir have been linked to a constellation of metabolic abnormalities, including elevated cholesterol levels, elevated triglyceride levels, insulin resistance, diabetes mellitus, and changes in body fat composition (eg, buffalo hump, abdominal obesity). The lipid abnormalities and body habitus changes are referred to as lipodystrophy. Although lipodystrophy is commonly associated with PIs, it has been seen also in HIV-infected persons who have never been treated with these agents. In particular, the lipodystrophy effects seen in patients receiving ART appears to be more related to the nucleoside toxicity and in particular to the thymidine analogs ( stavudine and zidovudine).

Of the different manifestations of lipodystrophy, the dyslipidemias that occur are of particular concern because of the likelihood that increased levels of cholesterol and triglycerides will result in increased prevalence of heart disease. All patients taking PIs or NRTIs should have fasting serum cholesterol, low-density lipoprotein (LDL) cholesterol, and triglyceride levels performed every 3–6 months. Clinicians should calculate the Framingham 10-year coronary heart disease risk (see Chapter 28) and consider initiating dietary or drug therapy (or both) to achieve target LDL levels depending on the individual’s risk factors. Patients who are unable to meet their LDL goal based solely on dietary interventions should be given pravastatin (20 mg daily orally) or atorvastatin (10 mg daily orally). Lovastatin and simvastatin should be avoided because of their interactions with PIs. Fish oil (3000 mg daily) combined with exercise and dietary counseling has been found to decrease triglycerides levels by 25%. Patients with persistently elevated fasting serum triglyceride levels of 500 mg/dL or more who do not respond to dietary intervention should be treated with gemfibrozil (600 mg twice daily prior to the morning and evening meals).

A. Indinavir—The standard dose of indinavir is 800 mg orally three times a day, although it is usually dosed twice daily in combination with ritonavir. Nausea and headache are common complaints with this drug. Indinavir crystals are present in the urine in approximately 40% of patients; this results in clinically apparent nephrolithiasis in about 15% of patients receiving indinavir. Lower urinary tract symptoms and acute kidney injury also have been reported. Patients taking this drug should be instructed to drink at least 48 ounces of fluid a day to ensure adequate hydration in an attempt to limit these complications. Mild indirect hyperbilirubinemia is also commonly observed in patients taking indinavir but is not an indication for discontinuation of the drug.

B. Saquinavir—Saquinavir is formulated only as a hardgel capsule (Invirase). It should only be used with ritonavir (1000 mg of hard-gel saquinavir with 100 mg of ritonavir orally twice daily). The soft-gel capsule (Fortovase) has been removed from the market in the United States. The most common side effects with saquinavir are diarrhea, nausea, dyspepsia, and abdominal pain.

C. Ritonavir—Use of this potent PI at full dose (600 mg orally twice daily) has been limited by its inhibition of the cytochrome P450 pathway causing a large number of drug–drug interactions and by its frequent side effects of fatigue, nausea, and paresthesias. However, it is widely used in lower dose (eg, 100 mg daily to 100 mg twice daily) as a booster of other PIs.

D. Nelfinavir—Nelfinavir is the only PI for which ritonavir boosting is not recommended. Unboosted nelfinavir is
Tipranavir is the only nonpeptidic PI currently approved by the US Food and Drug Administration (FDA). Because of its unique structure, it is active against some strains of HIV that are resistant to other PIs. It is dosed with ritonavir (two 250 mg capsules of tipranavir with two 100 mg capsules of ritonavir orally twice daily with food). The most common side effects are nausea, vomiting, diarrhea, fatigue, and headache. Tipranavir/ritonavir has been also associated with liver damage and should be used very cautiously in patients with underlying liver disease. Reports of intracranial hemorrhage in patients taking tipranavir-containing regimens have raised additional safety concerns about this potent PI. Because it is a sulfated-containing drug, its use should be closely monitored in patients with sulfal allergy.

3. Nonnucleoside reverse transcriptase inhibitors—NNRTIs inhibit reverse transcriptase at a site different from that of the nucleoside and nucleotide agents described above. All five NNRTIs have shown antiviral activity as measured by HIV viral load and CD4 responses. The major advantage of the NNRTIs is that three of them (efavirenz, rilpivirine, and nevirapine) have potencies comparable to that of PIs, at least for patients with viral loads under 100,000 copies/mL—with lower pill burden and fewer side effects. In particular, they do not appear to cause lipodystrophy; patients with cholesterol and triglyceride elevations who are switched from a PI to an NNRTI may have improvement in their lipids. The resistance patterns of the NNRTIs are distinct from those of the PIs, so their use still leaves open the option for future PI use.

The NNRTIs can be used with PIs in patients who are difficult to suppress on simpler regimens or when it is difficult to identify at least two nucleoside/nucleotide agents to which the patient is not resistant. Because these agents may cause alterations in the clearance of PIs, dose modifications may be necessary when these two classes of medications are administered concomitantly. There is a high degree of cross-resistance between the “first generation” NNRTIs, such that resistance to one drug in this class uniformly predicts resistance to other drugs. However, etravirine appears to have consistent antiviral activity in patients with prior exposure and resistance to nevirapine, efavirenz, or delavirdine. In particular, the K103N mutation does not appear to have an impact on etravirine (or rilpivirine). There is no therapeutic reason for using more than one NNRTI at the same time.
A. **Efavirenz**—The major advantages of efavirenz is that it can be given once daily in a single dose (600 mg orally), and it is available in a once-daily fixed-dose combination with tenofovir and emtricitabine in a single pill (Atripla). The combination is probably the best first choice for treatment-naïve patients without resistance to this regimen. The side effects are neurologic, with patients reporting symptoms ranging from lack of concentration and strange dreams to delusions and mania. Although the neurologic side effects of efavirenz subside over time, usually within a month, there are some patients who cannot tolerate these neurologic effects. Administration of efavirenz with food, especially fatty food, may increase its serum levels and consequent neurotoxicity. Due to teratogenicity, efavirenz should be avoided in women who wish to conceive or are already pregnant.

B. **Rilpivirine**—This drug, dosed at 25 mg once daily, is approved for persons initiating ART, and is equal in efficacy to efavirenz in patients with HIV viral loads below 100,000 copies/mL. Those with higher viral loads should be treated with efavirenz or a PI. As is true of efavirenz, rilpivirine is available in a once-daily fixed dose combination with tenofovir and emtricitabine (Complera) to be taken with a fatty meal. Rilpivirine has fewer neurologic side effects than efavirenz, making it a good choice as a first regimen, or an alternative regimen in patients who cannot tolerate the neurologic side effects of efavirenz.

C. **Nevirapine**—The target dose of nevirapine is 200 mg orally twice daily, but it is initiated at a dose of 200 mg once a day to decrease the incidence of rash, which is as high as 40% when full doses are begun immediately. If rash develops while the patient is taking 200 mg a day, liver enzymes should be checked and the dose should not be increased until the rash resolves. Patients with mild rash and no evidence of hepatotoxicity can continue to be treated with nevirapine. Nevirapine should not be used in treatment-naïve women with high CD4 counts (> 250/mL). Because of potential fatal hepatotoxicity, nevirapine should only be used in patients who cannot tolerate efavirenz. An extended-release formulation of nevirapine (Viramune XR) allows for once-daily dosing (400 mg daily). In clinical trials, nevirapine XR was not inferior when compared with standard nevirapine (both forms of nevirapine were combined with tenofovir/emtricitabine). This XR formulation potentially provides another once daily NNRTI regimen for first-line ART, although there has yet to be a direct comparison to any of the currently preferred first-line ART regimens (see below).

D. **Delavirdine**—Of the available NNRTIs, delavirdine is used the least largely because of its less convenient dosing and pill burden compared with the other available NNRTIs. Unlike nevirapine and efavirenz, delavirdine inhibits P450 cytochromes rather than inducing these enzymes. This means that delavirdine can act like ritonavir and boost other antiretrovirals, although delavirdine is not as potent as ritonavir in this capacity. The dosage is 400 mg orally three times a day. The major side effect is rash.

E. **Etravirine**—Etravirine is an NNRTI approved for the treatment of patients with prior NNRTI intolerance or resistance. Etravirine has been shown to be effective even when some degree of NNRTI-resistance is present, making it a true “second generation” drug in this class. Etravirine dosage is one 200 mg tablet twice daily. It should be used with a PI and a nucleoside/nucleotide analog and not just with two nucleoside/nucleotide analogs. The most common side effects are nausea and rash; rarely, the rash can be severe (toxic epidermal necrolysis). Patients with signs of severe rash or hypersensitivity reactions should immediately discontinue the drug. Prior rash due to treatment with one of the other NNRTIs does not make rash more likely with etravirine. Etravirine should not be taken by people with severe liver disease or administered with tipranavir/ritonavir, fosamprenavir/ritonavir, atazanavir/ritonavir, full-dose ritonavir, or PIs without low-dose ritonavir.

4. **Entry inhibitors**

A. **Enfuvirtide**—Enfuvirtide (Fuzeon) is known as a fusion inhibitor; it blocks the entry of HIV into cells by blocking the fusion of the HIV envelope to the cell membrane. The addition of enfuvirtide to an optimized antiretroviral regimen improved CD4 counts and lowered viral loads in heavily pretreated patients with multidrug-resistant HIV. Unfortunately, resistance develops rapidly in patients receiving nonsuppressive treatment. The dose is 90 mg by subcutaneous injection twice daily; unfortunately, painful injection site reactions develop in most patients, which makes long-term use problematic.

B. **Maraviroc**—Maraviroc is a CCR5 co-receptor antagonist. Drugs in this class prevent the virus from entering uninfected cells by blocking the CCR5 co-receptor. Unfortunately, this class of entry inhibitors is only active against “CCR5-tropic virus.” This form of the HIV-1 virus tends to predominate early in infection, while so-called “dual/mixed tropic virus” (which utilizes either R5 or CXCR4 co-receptors) emerges later as infection progresses. Approximately 50–60% of previously treated HIV-infected patients have circulating CCR5-tropic HIV. The drug has been shown to be effective in HIV-infected persons with ongoing viral replication despite being heavily treated and who have CCR5-tropic virus. Tropism testing should be performed before beginning the medication. The dose of maraviroc is 150–300 mg orally twice daily, based on the other drugs the patient is taking at the time. Common side effects are cough, fever, rash, musculoskeletal problems, abdominal pain, and dizziness; however, maraviroc is generally well tolerated with limited impact on serum lipids.

5. **Integrase inhibitors**

A. **Raltegravir**—Raltegravir is an HIV integrase inhibitor. Integrase inhibitors slow HIV replication by blocking the HIV integrase enzyme needed for the virus to multiply. Raltegravir was impressively effective (when combined with other active drugs) in the treatment of HIV-infected patients with documented resistance to at least one drug in each of the three main classes of antiretroviral medications
Clinical trials of integrase inhibitors reveal a consistent pattern of more rapid decline in viral load compared with more standard PI/r or NNRTI-based regimens. The clinical significance of this observation is unclear. Despite the impressive antiviral potency of this new class of antiretroviral drugs, high-level resistance to integrase inhibitors emerges quickly in the setting of virologic failure (much like with the NNRTIs). Therefore, it is critical that raltegravir be used in combination with other active antiretroviral agents.

Studies in treatment-naive patients have demonstrated that raltegravir in combination with tenofovir/emtricitabine is as effective as the current first-line choice of efavirenz/tenofovir/emtricitabine for daily treatment and has fewer side effects. Furthermore, the CD4 response appeared better in patients treated with the raltegravir combination. Raltegravir is approved by the FDA for treatment-naive patients. The dose of raltegravir is 400 mg orally twice daily. Common side effects are diarrhea, nausea, and headache.

B. Elvitegravir—Elvitegravir is another integrase inhibitor that is in late stage development. The dose is 125 mg once daily, given with ritonavir (100 mg) for boosting. Elvitegravir showed impressive short-term virologic responses in phase 2 studies and is expected to be approved in 2012.

6. Constructing regimens—There is now little debate about the necessity for combining drugs to achieve long-term suppression of HIV and its associated clinical benefit. Only combinations of three or more drugs have been able to decrease HIV viral load by 2–3 logs and allow long-term suppression of HIV RNA to below the threshold of detection.

Current evidence supports the use of Truvada (tenofovir and emtricitabine) as the “nucleoside/nucleotide backbone” combined with efavirenz as the initial regimen. This regimen has been shown to be more effective and better tolerated than Combivir (zidovudine and lamivudine) and Epzicom (abacavir/lamivudine). It has the advantages of once daily dosing and is available as a single pill (Atripla and Complera). Because 8–10% of newly infected persons in some urban areas of the United States have NNRTI resistance, resistance testing is not required. This can be complicated because of the potential for cross-resistance between drugs within a class. For example, the resistance patterns of lopinavir/ritonavir and indinavir are overlapping, and patients with virus resistant to these agents are unlikely to respond to nelfinavir or saquinavir even though they have never received treatment with these agents. Similarly, the resistance patterns of nevirapine and efavirenz are overlapping. With several new classes of drugs and new generations of existing drug classes now available, the ability to provide fully suppressive regimens even to patients with extensive treatment experience and drug resistance has become more realistic. The goal of therapy, therefore, should be to fully suppress viral loads to < 50 copies/mL even for highly treatment-experienced patients.

In addition to taking a careful history of what antiretroviral agents a patient has taken and for how long, genotypic and phenotypic resistance testing can provide useful information in designing second-line regimens. Whatever regimen is chosen, patients should be coached in ways to improve adherence. For certain populations (eg, unstably housed individuals), specially tailored programs that include drug dispensing are needed.

Rarely, it is impossible to construct a tolerable regimen that fully suppresses HIV. In such cases, clinicians and...
patients should consider their goals. Patients maintained on effective antiretroviral agents often benefit from these regimens (eg, higher CD4 counts, fewer opportunistic infections) even if their virus is detectable. In some cases, patients may request a drug holiday during which they are taken off all medications. Patients often immediately feel better because of the absence of drug side effects. Unfortunately, structured treatment interruptions generally result in viral rebound and rapid CD4 decline. Compared with patients who continue their regimens without interruption, those who interrupt their treatment fare poorly, with increased morbidity and mortality from both HIV-related and non-HIV-related causes.

7. The challenge of drug resistance—HIV-1 drug resistance limits the ability to fully control HIV replication and is a leading cause for antiretroviral regimen failure. Resistance has been documented for all currently available antiretrovirals including the newer classes of fusion inhibitor, CCR5 inhibitors, and integrase inhibitors. The problem of drug resistance is widespread in HIV-infected patients undergoing treatment in countries where ART is widely available. However, recent reports suggest that the degree of high level resistance is declining in the past few years, which is likely related to better tolerated, easier to use, and more efficacious antiretroviral agents. Patients who have taken various antiretroviral regimens and who now have resistant HIV-1 represent a major challenge for the treating clinician. Resistance is now also documented in patients who are ART-naive, but who have been infected with a drug resistant strain—“primary resistance.” Cohort studies of antiretroviral treatment–naive patients entering care in North America and Western Europe show that roughly 10–12% (and as high as 25%) of recently infected individuals have been infected with a drug-resistant strain of HIV-1.

Current expert guidelines recommend resistance testing as part of standard baseline testing in all patients. Resistance testing is also recommended for patients who are on an antiretroviral regimen and have suboptimal viral suppression (ie, viral loads > 1000 copies/mL). Both genotypic and phenotypic tests are commercially available and in randomized controlled studies their use has been shown to result in improved short-term virologic outcomes compared to making treatment choices without resistance testing. Furthermore, multiple retrospective studies have conclusively demonstrated that resistance tests provide prognostic information about virologic response to newly initiated therapy that cannot be gleaned from standard clinical information (ie, treatment history, examination, CD4 count, and viral load tests).
Because of the complexity of resistance tests, many clinicians require expert interpretation of results. In the case of genotypic assays, results may show that the mutations that are selected for during ART are drug-specific or contribute to broad cross-resistance to multiple drugs within a therapeutic class. An example of a drug-specific mutation for the reverse transcriptase inhibitors would be the M184V mutation that is selected for by lamivudine or emtricitabine therapy—this mutation causes resistance only to those two drugs. Conversely, the thymidine analog mutations (“TAMs”) of M41L, D67N, K70R, L210W, T215Y/F, and T219Q/K/E are selected for by either zidovudine or stavudine therapy, but cause resistance to all the drugs in the class and often extend to the nucleotide inhibitor tenofovir when three or more of these TAMs are present. Further complicating the interpretation of genotypic tests is the fact that some mutations that cause resistance to one drug can actually make the virus that contains this mutation more sensitive to another drug. The M184V mutation, for example, is associated with increased sensitivity to zidovudine, stavudine, and tenofovir. The most common mutations associated with drug resistance and cross-resistance patterns for NRTIs, NNRTIs, PIs, and integrase inhibitors can be found at http://hivdb.stanford.edu. Phenotypic tests also require interpretation in that the distinction between a resistant virus and sensitive one is not fully defined for all available drugs.

Both methods of resistance testing are limited by the fact that they may measure resistance in only some of the viral strains present in an individual. Resistance results may also be misleading if a patient is not taking antiretroviral medications at the time of testing. Thus, resistance results must be viewed cumulatively—i.e., if resistance is reported to an agent on one test, it should be presumed to be present thereafter even if subsequent tests do not give the same result.

Despite the prevalence of resistance in patients who have not responded to multiple prior treatment regimens and given the availability of new class drugs and new generation drugs, virtually all patients—no matter how much resistance is present—can be treated with a combination of ART that should be fully suppressive.

### When to Admit

Patients with opportunistic infections who are acutely ill (e.g., who are febrile, who have had rapid change of mental status, or who are in respiratory distress) or who require intravenous medications.

### Course & Prognosis

With improvements in therapy, patients are living longer after the diagnosis of AIDS. A population-based study conducted in Denmark found that HIV-infected persons at age 25 years without hepatitis C had a life expectancy of 39 additional years. Unfortunately, not all HIV-infected persons have access to treatment. Studies consistently show less access to treatment for blacks, the homeless, and injection drug users. In addition to access to treatment, sustaining lower mortality will require developing new treatments for patients in whom resistance to existing agents develops. For patients whose disease progresses even though they are receiving appropriate treatment, meticulous palliative care must be provided (see Chapter 5), with attention to pain control, spiritual needs, and family (biologic and chosen) dynamics.

### When to Refer

- Clinicians with limited experience in HIV/AIDS should refer HIV-infected patients to specialists with experience, given the increasing number and complexity of treatment regimens available.
- Extra efforts should be made to obtain specialty consultation for those patients with detectable viral loads on ART; those intolerant of standard medications; those in need of systemic chemotherapy; and those with complicated opportunistic infections, particularly when invasive procedures or experimental therapies are needed.

HERNAN HERPESVIRUSES

Herpesviruses cause a wide spectrum of human disease. Eight identified human herpesviruses (HHVs) include herpes simplex virus (HSV) (type 1), HSV (type 2), varicella zoster virus (VZV) (type 3), Epstein–Barr (EBV) infectious mononucleosis virus (type 4), and cytomegalovirus (CMV) (type 5). A sixth type (HHV-6) is identified as a causative agent of roseola (exanthema subitum), and a seventh (HHV-7) is serologically associated with several syndromes. Finally, human herpesvirus 8 (HHV-8) is linked with Kaposi sarcoma (see Chapter 31) and primary effusion lymphoma.

Subclinical primary infection with the herpesviruses is more common than clinically manifest illness. Each persists in a latent state for the remainder of the person’s life. With HSV and VZV, virus remains latent in sensory ganglia. Upon reactivation, lesions appear in the distal sensory nerve distribution. As a result of disease, drug, or radiation-induced immunosuppression, virus reactivation may lead to widespread lesions in affected organs such as the viscera or the central nervous system (CNS). Severe or fatal illness may occur in infants and immunodeficient persons. Herpesviruses can induce cell transformation, hence the association with certain malignancies, such as Burkitt lymphoma and nasopharyngeal carcinoma (with EBV) or primary effusion lymphoma and Kaposi sarcoma (with HHV-8).

1. Herpesviruses 1 & 2

ESSENTIALS OF DIAGNOSIS

- Spectrum of illness from stomatitis and urogenital lesions to facial nerve paralysis (Bell palsy) and encephalitis.
- Variable intervals between exposure and clinical disease, since HSV causes both primary (often subclinical) and reactivation disease.
- Successful management with acyclovir, valacyclovir, or famciclovir.

General Considerations

Herpesviruses 1 and 2 affect primarily the oral and genital areas, respectively. Risk factors for HSV transmission include black race, female gender, a history of sexually transmitted infections, an increased number of partners, contact with commercial sex workers, lower socioeconomic status, young age at onset of sexual activity, and total duration of sexual activity. Therefore, seroprevalence of both viruses increases with age, and the seroprevalence of HSV-2 increases with sexual activity. Currently, 16% of the population in the United States is seropositive for HSV-2; of these, only 10–25% have recognized disease. Asymptomatic shedding of either virus is common, especially following primary infection or symptomatic recurrences, and may be responsible for transmission. Asymptomatic HSV-2–infected individuals shed the virus less frequently than those with symptomatic infection. Disease is typically a manifestation of reactivation. Total and subclinical shedding of HSV-2 virus decrease after the first year of initial infection, although viral shedding continues for years thereafter. Higher than expected rates of HSV-2 lesions occur among women in the postpartum period and also among women who have sex with women.

Although HSV-2 is the most common cause of genital ulcers in the developed world, HSV-1 is increasingly recognized as causing primary urogenital infections. Genital recurrences are much more frequent with HSV-2 and gradually decrease over time, whereas HSV-1 recurrences are rare after the first year. HSV-2 seropositivity increases the risk of HIV acquisition (it is threefold higher among persons who are HSV-seropositive than among those who are HSV-2 seronegative), and reactivates more frequently in advanced HIV infection. HIV replication is increased by interaction with HSV proteins. Suppression of HSV-2 decreases HIV-1 plasma levels and genital tract shedding of HIV, which can contribute to a reduction in sexual transmission of HIV-1.

Clinical Findings

A. Symptoms and Signs

1. Mucocutaneous disease—HSV-1 mucocutaneous disease largely involves the mouth and oral cavity (“herpes
3. Neonatal and congenital infection—Both herpesviruses can infect the fetus and induce congenital malformations (organomegaly, bleeding, and CNS abnormalities). Maternal infection during the third trimester is associated with the highest risk of neonatal transmission, but about 70% of these infections are asymptomatic or unrecognized. Neonatal transmission during delivery, however, is more common than intrauterine infection. Invasive fetal monitoring and vacuum or forceps delivery can increase the risk of herpesvirus transmission.

4. Central nervous system disease—Herpes simplex encephalitis is predominantly caused by HSV-1 and presents with nonspecific symptoms: a flu-like prodrome, followed by headache, fever, behavioral and speech disturbances, and focal or generalized seizures. The temporal lobe is often involved. Untreated disease and presentation with coma carry a high mortality rate, with many survivors suffering neurologic sequelae. Herpes encephalitis does not occur disproportionately among immunosuppressed persons and a subset of pediatric herpes encephalitis is associated with toll-like receptor 3 deficiencies or abnormalities.

Both HSV-1 and HSV-2 are increasingly recognized as a cause of mild, nonspecific neurologic symptoms and are also associated with benign recurrent lymphocytic (Mollaret) meningitis. Primary HSV-2 infection in women often presents as aseptic meningitis. Recurrent meningitis from HSV-2 occurs in both younger and older individuals. HSV-1 infection may enhance the development of Alzheimer disease by promoting tau phosphorylation.

5. Disseminated infection—Disseminated HSV infection occurs in the setting of immunosuppression, either primary or iatrogenic, or rarely with pregnancy. In disseminated disease, skin lesions are not always present. Disseminated skin lesions are a particular complication in patients with atopic eczema (eczema herpeticum) and burns. Pneumonia can occur in both immunocompetent and immunosuppressed persons.

6. Bell palsy—An association between HSV-1 and Bell palsy is established.

7. Esophagitis and proctitis—HSV-1 can cause esophagitis in immunocompromised patients, particularly those with AIDS. The lesions are smaller and deeper than those observed in patients with CMV esophagitis or with other herpesvirus known to cause esophagitis in immunocompromised hosts. HSV-1 is also postulated to activate mononuclear cells in the pathogenesis of achalasia. Proctitis often occurs mainly in men who have sex with men.

8. Erythema multiforme—Herpes simplex viruses remain, along with certain drugs, a leading cause of erythema multiforme and of the more severe Stevens–Johnson syndrome.

9. Other—HSV is the cause of approximately 1% of cases of acute liver failure, particularly in pregnant women and immunosuppressed patients. When it occurs, the mortality of fulminant hepatitis is nearly 75%. An HSV lower respiratory tract infection of unknown clinical significance is common in mechanically ventilated patients. Evidence suggests that this finding is an indicator of a poor clinical

**Figure 32–1.** Herpetic whitlow. (Used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tseng C. The Color Atlas of Family Medicine. McGraw-Hill, 2009.)
B. Laboratory Findings

1. **Mucocutaneous disease**—Diagnosis is usually made clinically, but viral cultures of vesicular fluid or direct fluorescent antibody staining of scraped lesions remain the standard of diagnosis. Intranuclear inclusion bodies and multinucleated giant cells on a Tzanck preparation or Calcofluor stain are indicative of herpetic infection. Polymerase chain reaction (PCR) is a more sensitive diagnostic assay. A DNA microarray test for simultaneous detection of HSV-1, HSV-2, VZV, CMV, EBV, HHV-6, and adenovirus in immunocompromised patients is found to be sensitive, specific, cost-effective, and time saving. Type-specific serologies are useful for counseling HIV-infected individuals; pregnant women; sexual partners of persons infected with HSV; and those with an uncertain clinical history, high-risk behavior, or increased number of sexual partners.

2. **Ocular disease**—Herpes keratitis is diagnosed by branching (dendritic) ulcers that stain with fluorescein. The extent of epithelial injury in herpetic keratitis correlates well with PCR positivity.

3. **Encephalitis and recurrent meningitis**—Cerebrospinal fluid pleocytosis is common, with a similar increase in the number of red cells. HSV DNA PCR of the cerebrospinal fluid is a rapid, sensitive, and specific tool for early diagnosis. Antibodies to HSV in cerebrospinal fluid can confirm the diagnosis but appear late in the course of the disease. Viral culture shows a sensitivity of only 10%. MRI scanning is often a useful adjunct showing increased signal in the temporal and frontal lobes. Temporal lobe seizure foci may be shown on electroencephalograms (EEGs).

4. **Esophagitis and proctitis**—Esophagitis is diagnosed by endoscopic biopsy and cultures. Proctitis may be diagnosed by rectal swab for PCR or culture, or both, although complicated cases may require biopsy.

5. **Pneumonia**—Pneumonia is diagnosed by clinical, pathologic, and radiographic findings. The CT findings include diffuse or multifocal areas of ground-glass attenuation or consolidative changes or both and are best confirmed using high-resolution CT techniques.

### Treatment & Prophylaxis

Drugs that inhibit replication of HSV-1 and HSV-2 include trifluridine and vidarabine (both for keratitis), acyclovir and related compounds, foscarnet, and cidofovir (Table 32–1).

### A. Mucocutaneous Disease

While treatment is often not necessary in immunocompetent patients, it can ameliorate and shorten the duration of symptoms if initiated early. Oral therapy for 7–10 days is the preferred treatment for **primary genital infection** and includes acyclovir (200 mg five times a day or 400 mg three times a day), valacyclovir (1 g twice daily), or famciclovir (250 mg three times daily). **Primary herpes labialis** is most often treated with oral acyclovir (same doses and duration as for genital infection). Intravenous acyclovir (5–10 mg/kg every 8 hours for 7–14 days) should be considered in immunosuppressed patients. Topical 1% hydrocortisone cream in combination with 5% acyclovir cream is also safe and effective in the treatment of recurrent herpes simplex labialis.

For **recurrent genital disease**, acyclovir (800 mg orally three times daily for 2–5 days), valacyclovir (500 mg orally twice daily for 3 days or 1 g once a day for 5 days), or famciclovir (1 g orally twice daily for 1 day or 500 mg initial dose followed by 250 mg twice daily for 2 days) are all acceptable alternatives. Patient-initiated therapy with a short course (1–2 day regimens) of antiviral agents at first symptoms of recurrence or prodrome is a frequently used approach. For the treatment of recurrences of herpes labialis, lesions heal faster with topical penciclovir than with topical acyclovir. Docosanol cream offers modest benefit.

Atypical isolates, large ulcerations, new lesions, or poor response to therapy suggest acyclovir resistance, which often occurs in immunodeficient patients. Alternatives include high dose acyclovir (4–5 g), which is effective in treating proctitis in the HIV-positive population, or foscarnet (40–60 mg/kg intravenously every 8 hours), adjusting the dose interval in patients with kidney dysfunction. Cidofovir is used in rare cases of infection resistant to both acyclovir and foscarnet.

Patients with frequent recurrent genital infections may be given **secondary prophylaxis** with acyclovir, 400 mg twice a day; valacyclovir, 500–1000 mg once daily; or famciclovir, 250 mg twice a day. For herpes labialis, valacyclovir, 500 mg daily, is the best option. Sunscreen may be useful for recurrences associated with sunlight exposure. Advantages of suppressive therapy include a significant reduction in acquisition of disease among the HSV-2 discordant heterosexual partners and a likely reduced transmission in persons with multiple partners, including men who have sex with men and patients with recent HSV-2 infection. AIDS patients with a history of mucocutaneous disease should continue receiving suppressive therapy unless a sustained improvement of immune status occurs. Among the HIV-infected, the use of highly active antiretroviral therapy (HAART) is associated with a shortened duration of HSV-1 and -2 lesions. The CAPRISA 004 trial recently showed that although topical tenofovir 1% gel was associated with a significant decrease in HSV-2 acquisition, there was no impact in the shedding rates among coinfected adults.

### B. Keratitis

For the treatment of acute epithelial keratitis, topical antiviral agents (ophthalmic trifluridine, vidarabine,

1Agents used exclusively in the management of HIV infection and AIDS are found in Chapter 31.
2Available through the Centers for Disease Control and Prevention Emergency Use Authorization.

CNS, central nervous system; CSF, cerebrospinal fluid; HSV, herpes simplex virus; VZV, varicella-zoster virus; HBV, hepatitis B virus; CMV, cytomegalovirus; HPV, human papillomavirus; HCV, hepatitis C virus; RSV, respiratory syncytial virus.
acyclovir, and ganciclovir) are all nearly equivalent in efficacy and are recommended. Combination of topical antiviral agents with interferon or debridement (or both) hastens healing. Intravenous acyclovir is used for acute retinal necrosis. Oral famciclovir is a reasonable alternative, especially in patients unable to tolerate intravenous therapy and when acyclovir resistance is present. The usage of topical corticosteroids may exacerbate the infection, although systemic corticosteroids may help with selected cases of stromal infection. Long-term treatment (> 1 year) with acyclovir at a dosage of 800 mg/d orally decreases recurrence rates of keratitis, conjunctivitis or blepharitis due to HSV.

**C. Neonatal Disease**

Intravenous acyclovir (20 mg/kg every 8 hours for 14–21 days) is effective for the treatment of disseminated lesions in neonatal disease. Counseling with serologic screening should be offered to pregnant mothers. The use of maternal antenatal suppressive therapy with acyclovir (typically, 400 mg three times daily) beginning at 36 weeks gestation decreases the presence of detectable HSV, the rates of recurrence at delivery, and the need for cesarean section. Cesarean section is recommended for pregnant women with active genital lesions or typical prodromal symptoms.

**D. Encephalitis and CNS Meningitis**

Because of the need for rapid treatment to decrease mortality and neurologic sequelae, intravenous acyclovir (10 mg/kg every 8 hours for 10 days or more, adjusting for kidney dysfunction) should be started in those patients with suspected HSV encephalitis, stopping only if another diagnosis is established. If the PCR of cerebrospinal fluid is negative but clinical suspicion remains high, treatment should be continued for 10 days because the false-negative rate for PCR can be as high as 25% (especially in children) and acyclovir is relatively nontoxic. Long-term neurologic sequelae are common and late pediatric relapse is recognized. Acyclovir resistance in a case of herpes simplex encephalitis is reported. Aseptic meningitis may also require a course of intravenous acyclovir or valacyclovir.

**E. Disseminated Disease**

Disseminated disease responds best to parenteral acyclovir when treatment is initiated early.

**F. Bell Palsy**

Prednisolone, 25 mg orally twice daily for 10 days started within 72 h of onset, significantly increases the rate of recovery. Data on antiherpetic antiviral agents are equivocal; according to one study, valacyclovir (but not acyclovir), 1 g orally daily for 5 days, plus corticosteroid therapy may be beneficial if started within 7 days of symptom onset. In patients with severe or complete facial paralysis, such antiviral therapy is often administered but without a firm proof of efficacy.

**G. Esophagitis and Proctitis**

Patients with esophagitis should receive either intravenous acyclovir (5–10 mg/kg every 8 hours) or oral acyclovir (400 mg five times daily). Maintenance therapy for AIDS patients is also with acyclovir (400 mg three to five times daily). Proctitis is treated with similar dosages and usually responds within 5 days.

**H. Erythema Multiforme**

Suppressive therapy with oral acyclovir (400 mg twice a day for 6 months) decreases the recurrence rate of HSV-associated erythema multiforme. Valacyclovir (500 mg twice a day) may be effective in cases unresponsive to acyclovir.

**Prevention**

Besides antiviral suppressive therapy, prevention also requires counseling and the use of condom barrier precautions during sexual activity. Disclosure of partner status is associated with about a 50% reduction in the HSV-2 acquisition. Arguments favoring partner testing include confirming exposure, assistance with management, reducing the risk of transmission, and aiding in public health strategies. Male circumcision is associated with a lower incidence of acquiring HSV-2 infection.

Preventing spread to hospital staff and other patients from cases with mucocutaneous, disseminated, or genital disease requires isolation and the usage of hand-washing and gloving–gowning precautions. Staff with active lesions (eg, whitlows) should not have contact with patients. Asymptomatic transmission occurs, especially with HSV-2. Initial success with a glycoprotein vaccine did not persist with studies on a larger scale where the vaccine was found to be ineffective. Current vaccine trials focus on HSV-2 peptides, plasmid expressing peptides (DNA vaccine), viral vectors, and attenuated/repllication-defective versions of HSV-2.

The incidence and severity of herpes zoster ("shingles"), which affects up to 25% of persons during their lifetime, increases with age due to an age-related decline in immunity against VZV. More than half of all patients in whom herpes zoster develops are older than 60 years, and the incidence of herpes zoster reaches 10 cases per 1000 patient-years by age 80 (by which time 50% are infected with VZV). The annual incidence in the United States of 1 million cases is increasing as the population ages. Populations at increased risk for varicella-zoster–related diseases include immunosuppressed persons and persons receiving biologic agents (tumor necrosis factor inhibitors).

### General Considerations

Varicella zoster virus (VZV), or HHV-3, disease manifestations include chickenpox (varicella) and shingles (herpes zoster). Chickenpox generally presents during childhood; has an incubation period of 10–20 days (average 2 weeks); and is highly contagious, spreading by inhalation of infectious droplets or contact with lesions.

### Clinical Findings

#### A. Varicella

1. **Symptoms and signs**—Fever and malaise are mild in children and more marked in adults. The pruritic rash begins prominently on the face, scalp, and trunk, and later involves the extremities (Table 32–2). Maculopapules

</tbody>
</table>

severe in older patients and immunocompromised persons. In the latter, atypical presentations, including widespread dissemination in the absence of skin lesions, are often described.

There is a small increased risk of Guillain-Barré syndrome for at least 2 months after an acute herpes zoster attack.

2. Laboratory findings—Diagnosis is usually made clinically, with confirmation by direct immunofluorescent antibody staining or PCR of scrapings from lesions. Multinucleated giant cells are usually apparent on a Tzanck smear or Calcofluor stain of material from the vesicle bases. Leukopenia and subclinical transaminase elevation are often present and thrombocytopenia occasionally occurs.

A varicella skin test and interferon-gamma enzyme-linked immunospot (ELISPOT) can screen for VZV susceptibility.

B. Herpes Zoster

Herpes zoster (“shingles”) usually occurs among adults, but cases are reported among infants and children. Skin lesions resemble those of chickenpox. Pain is often severe and commonly precedes the appearance of rash. Lesions follow a dermatomal distribution, with thoracic and lumbar roots being the most common. In most cases, a single unilateral dermatome is involved, but occasionally, neighboring and distant areas are involved. Lesions on the tip of the nose, inner corner of the eye, and root and side of the nose (Hutchinson sign) indicate involvement of the trigeminal nerve (herpes zoster ophthalmicus). Facial palsy, lesions of the external ear with or without tympanic membrane involvement, vertigo and tinnitus, or deafness signify geniculate ganglion involvement (Ramsay Hunt syndrome or herpes zoster oticus). Shingles is a particularly common and serious complication among patients with multiple myeloma who receive bortezomib therapy, and it also occurs among patients with systemic lupus erythematosus receiving corticosteroids and immunomodulators. Contact with patients who have varicella does not appear to be a risk factor for zoster.

Complications

A. Varicella

Secondary bacterial skin superinfections, particularly with group A β-hemolytic streptococci and Staphylococcus aureus, are the most common complications in children. Cellulitis, erysipelas, and scarlet fever are described. Bullous impetigo and necrotizing fasciitis are less often seen. Other associations with varicella include epiglottitis, necrotizing pneumonia, osteomyelitis, septic arthritis, epidural abscess, meningitis, endocarditis, and purpura fulminans. Toxic shock syndrome can also develop.

Interstitial VZV pneumonia is more common in adults (especially smokers, HIV-infected patients, and pregnant women) and may result in acute respiratory distress syndrome (ARDS). After healing, numerous densely calcified lesions are seen throughout the lung fields on chest radiographs.
Historically, neurologic complications developed in about 1 in 2000 children. Currently, cerebellar ataxia occurs at a frequency of 1:4000 in the young. A limited course and complete recovery are the rule. Encephalitis is similarly infrequent, occurs mostly in adults, and is characterized by delirium, seizures, and focal neurologic signs. Both mortality and long-term neurologic sequelae rates are about 10%. Ischemic strokes in the wake of acute VZV infection present a mean of 4 months after rashes and may be due to an associated vasculitis. Multifocal encephalitis, ventriculitis, myeloradiculitis, arterial aneurysm formation, and arteritis are also described in immunosuppressed, especially HIV-infected, patients.

Purpura fulminans is an extremely rare complication of varicella secondary to protein S deficiency resulting in diffuse intravascular coagulation and severe skin defects. VZV reactivation on rare occasions causes a hemophagocytic lymphohistiocytosis syndrome in severely immunocompromised patients.

Clinical hepatitis is uncommon and mostly presents in the immunosuppressed patient but can be fulminant and fatal. Reye syndrome (fatty liver with encephalopathy) also complicates varicella (and other viral infections, especially influenza B), usually in childhood, and is associated with aspirin therapy (see Influenza, below).

When contracted during the first or second trimesters of pregnancy, varicella carries a very small risk of congenital malformations, including cicatricial lesions of an extremity, growth retardation, microphthalmia, cataracts, chorioretinitis, deafness, and cerebrocortical atrophy. If varicella develops around the time of delivery, the newborn is at risk for disseminated disease.

**B. Herpes Zoster**

Postherpetic neuralgia occurs in 60–70% of patients who have herpes zoster and are older than 60 years. The pain can be prolonged and debilitating. Risk factors for postherpetic neuralgia include advanced age, female sex, the presence of a prodrome, and severity of rash or pain but not family history.

Other complications include the following: (1) bacterial skin superinfections; (2) herpes zoster ophthalmicus, which occurs with involvement of the trigeminal nerve and is a sight-threatening complication (especially when it involves the cornea or the iris), and is a marker for stroke over the ensuing year (Hutchinson sign is a marker of ocular involvement in the HIV-positive population); (3) rarely, unilateral ophthalmoplegia; (4) involvement of the geniculate ganglion of cranial nerve VII as well as cranial nerves V, VIII, IX, and X; (5) aseptic meningitis; (6) peripheral motor neuropathy; (7) transverse myelitis; (8) encephalitis; (9) acute cerebellitis; (10) stroke; (11) vasculopathy; (12) acute retinal necrosis; and (13) progressive outer retinal necrosis (largely among HIV infected persons). VZV is a major cause of Bell palsy in patients who are HSV seronegative. Diagnosis of neurologic complications requires the detection of VZV DNA or anti-VZV IgG in cerebrospinal fluid or the detection of VZV DNA in tissue. *Zoster sine herpete* (pain without rash) can also be associated with most of the above complications. Associations between recent attacks of zoster and the development of multiple sclerosis and Guillain-Barré syndrome are recognized.

**Treatment**

**A. General Measures**

In general, patients with varicella should be isolated until primary crusts have disappeared and kept at bed rest until afebrile. The skin is kept clean. Pruritus can be relieved with antihistamines, calamine lotion, and colloidal oatmeal baths. As an antipyretic, acetaminophen is used. Fingernails can be closely cropped to avoid skin excoriation and infection.

**B. Antiviral Therapy**

Acyclovir, 20 mg/kg (up to 800 mg per dose) orally four times daily for 3 days, should be given within the first 24 hours after the onset of varicella rash and should be considered for patients older than 12 years, secondary household contacts (disease tends to be more severe disease in secondary cases), patients with chronic cutaneous and cardiopulmonary diseases, and children receiving long-term therapy with salicylates (to decrease the risk of Reye syndrome). Experience with valacyclovir and famciclovir in these settings is scant.

In immunocompromised patients, in pregnant women during the third trimester, and in patients with extracutaneous disease (encephalitis, pneumonitis), antiviral therapy with high-dose acyclovir (30 mg/kg/d in three divided doses intravenously for at least 7 days) should be started once the diagnosis is suspected. Corticosteroids may be useful in the presence of pneumonia. Prolonged prophylactic acyclovir is important for thorough suppression of VZV reactivation in profoundly immunosuppressed patients.

For uncomplicated herpes zoster, acyclovir (800 mg orally five times daily) or valacyclovir (1 g orally three times daily) for 7 days is recommended. Therapy should start within the first 72 hours of the onset of the lesions. Intravenous acyclovir is used for extradermatomal complications of zoster, although acyclovir is not fully effective in retinal disease. A topical antiviral, sorivudine, appears to be a safe and well-tolerated adjuvant therapy to valacyclovir for treatment of acute herpes zoster. Foscarnet may be used for acyclovir-resistant VZV infections seen in immunosuppressed patients. The Ramsay Hunt syndrome is more resistant to antiviral therapy.

**C. Treatment of Complications**

Once established, postherpetic neuralgia may respond to gabapentin or lidocaine patches (FDA approved drugs for neuropathic pain). Tricyclic antidepressants, opioids, and capsicain cream are also widely used and effective. The epidural injection of corticosteroids and local anesthetics appears to modestly reduce herpetic pain at 1 month but is not effective for prevention of long-term postherpetic neuralgia. Secondary bacterial infections are treated with antibiotics providing coverage for staphylococci. The use of antiviral agents for postherpetic neuralgia is under further study.
**Prognosis**

The total duration of varicella from onset of symptoms to disappearance of cruds rarely exceeds 2 weeks. Fatalities are rare except in immunosuppressed patients.

Herpes zoster resolves in 2–6 weeks. Antibodies persist longer and at higher levels than with primary varicella. Eye involvement with herpes zoster necessitates periodic future examinations.

**Prevention**

Health care workers should be screened for varicella and vaccinated if seronegative. Patients with active varicella or herpes zoster are promptly separated from seronegative patients. For those with varicella, airborne and contact isolation is recommended, whereas for those with zoster, contact precautions are sufficient. For immunosuppressed patients with zoster, precautions should be the same as if the patient had varicella. Exposed serosusceptible patients should be placed in isolation and exposed serosusceptible employees should stay away from work between days 10 and 21 after exposure. Health care workers with zoster should receive antiviral agents during the first 72 hours of disease and withdraw from work until lesions are crusted. Postexposure prophylaxis should be evaluated (see below).

**A. Varicella**

1. **Vaccination**—Universal childhood vaccination against varicella is effective. The varicella vaccine (Varilrix) is safe and over 98.1% effective when given after 13 months of age. A single antigen live attenuated vaccine (VARIVAX) or a quadrivalent measles, mumps, rubella, and varicella vaccine (ProQuad) are available. The first dose should be administered at 12–15 months of age and the second at 4–6 years. Aspirin should be avoided for at least 6 weeks because of the risk of Reye syndrome. This vaccine is safe, well tolerated, but the quadrivalent vaccine is associated with a small risk of febrile seizures 5–12 days after vaccination among infants aged 12–23 months. Rashes, when secondary to the varicella vaccine, appear 15–42 days after vaccination. Rare cases of zoster among children who received the varicella vaccine are attributable to delayed vaccination (after age 5), severe asthma, and developmental disorders. Such complications appear to occur less often among American children of African ancestry.

For serosusceptible individuals older than 13 years, two doses of varicella vaccine (single antigen) administered 4–8 weeks apart is recommended. For those who received a single dose in the past, a catch-up second dose is advised, especially in the epidemic setting (where it is effective when it can be given during the first 5 days postexposure). Household contacts of immunocompromised patients should adhere to these recommendations. Susceptible pregnant women need to receive the first dose of vaccine before discharge after delivery and the second dose 4–8 weeks later. The quadrivalent vaccine MMRV can be used for the second doses of MMR and varicella in patients aged 15 months to 12 years and for the first dose in patients aged 48 months or older. (Before this age, the MMR and varicella vaccination can safely be given separately.)

The vaccine, administered 3 months apart, should also be considered for HIV-infected adolescents and adults with CD4 T lymphocyte counts ≥ 200 cells/mcL. The vaccine may also be given to patients with impaired humoral immunity, to patients receiving corticosteroids, and to patients with juvenile rheumatoid arthritis who receive methotrexate. Patients receiving high doses of corticosteroids for over 2 weeks may be vaccinated a month after discontinuation of the therapy. Patients with leukemia, lymphoma, or other malignancies whose disease is in remission and who have not undergone chemotherapy for at least 3 months may be vaccinated. Kidney and liver transplant patients should be vaccinated if they are susceptible to varicella.

The incidence of varicella in the United States has been reduced between 67% and 87% as a consequence of the varicella vaccine.

2. **Postexposure**—Postexposure vaccination is recommended for unvaccinated persons without other evidence of immunity. Varicella-zoster immune globulin (VZIG) (in short supply with production stopped in 2004) or Varizig (a lyophilized product available under expanded access since December 2007) should be considered for susceptible exposed patients who cannot receive the vaccine, including immunosuppressed patients, neonates from mothers with varicella around the time of delivery, exposed premature infants born from serosusceptible mothers at > 28 weeks of gestation, neonates born at < 28 weeks of gestation regardless of maternal serostatus, and pregnant women. No controlled studies have evaluated the use of acyclovir in this setting. VZIG is given by intramuscular injection in a dosage of 12.5 units/kg up to a maximum of 625 units, with a repeat identical dose in 3 weeks if a high-risk patient remains exposed. VZIG has no place in therapy of established disease.

Further information may be obtained by calling the Centers for Disease Control and Prevention’s Immunization Information Hotline (800-232-2522).

**B. Herpes Zoster**

A live attenuated VZV vaccine (ZOSTAVAX, 19,400 plaque forming units [pfu] of Oka/Merck strain) consists of varicella virus at a concentration at least 14 times that found in VARIVAX (1350 pfu). This vaccine should be offered to persons 60 years and older but cannot be used in children in place of varicella vaccine; if the vaccine is accidentally given to a child, the event should be reported to the CDC. In adults, the vaccine reduces the incidence of postherpetic neuralgia and herpes zoster by 67% and 51%, respectively. Before administration of zoster vaccine, patients do not need to be asked about their history of varicella (chickenpox) or have serologic tests to determine varicella immunity because the vaccine is safe, tolerated, and immunogenic in persons with a history of herpes zoster. A second dose of the zoster vaccine is not recommended because it does not boost VZV specific immunity beyond the levels achieved by the first dose. The attenuated VZV vaccine is safe and modestly immunogenic among HIV-infected persons with a CD4 count of at least 300 cells/mcL.
In 2009, the manufacturer advised against concurrent administration with 23-valent pneumococcal polysaccharide vaccine based on a study showing lower VZV titers; however, a subsequent larger study showed equal effectiveness among persons who received the vaccine at the same time when compared to those who received the vaccines 4 weeks apart. Consequently, the CDC continues to recommend the administration of both vaccines at the same visit. If a varicella vaccine is mistakenly administered to an adult instead of a zoster vaccine, the dose should be considered invalid and the patient should be administered a dose of zoster vaccine at the same visit. Prophylaxis with acyclovir, 800 mg orally twice daily, can be considered in patients at high risk for VZV reactivation (eg, allogeneic hematopoietic cell transplant patients).

3. Epstein–Barr Virus & Infectious Mononucleosis

**ESSENTIALS OF DIAGNOSIS**

- Malaise, fever, and sore throat, sometimes with exudates.
- Palatal petechiae, lymphadenopathy, splenomegaly, and, occasionally, a maculopapular rash.
- Positive heterophil agglutination test (Monospot).
- Atypical large lymphocytes in blood smear; lymphocytosis.
- Complications: hepatitis, myocarditis, neuropathy, encephalitis, airway obstruction secondary to lymph node enlargement, hemolytic anemia, thrombocytopenia.

**General Considerations**

Epstein-Barr virus (EBV, or human herpes virus-4 [HHV-4]) is one of the most ubiquitous human viruses, infecting > 95% of the adult population worldwide and persisting for the lifetime of the host. Infectious mononucleosis is a common manifestation of EBV and may occur at any age. In the United States, EBV infection usually develops in persons between the ages of 10 and 35 years, sporadically or epidemically. In the developing world, infectious mononucleosis occurs at younger ages and tends to be less symptomatic. Rare cases in the elderly occur usually without the full symptomatology. EBV is largely transmitted by saliva but can also be recovered from genital secretions. Saliva may remain infectious during convalescence, for 6 months or longer after symptom onset. The incubation period lasts several weeks (30–50 days).

**Clinical Findings**

**A. Symptoms and Signs**

The protean manifestations of infectious mononucleosis reflect the dissemination of the virus in the oral cavity and through peripheral blood lymphocytes and cell-free plasma. Fever, sore throat, fatigue, malaise, anorexia, and myalgia typically occur in the early phase of the illness. Physical findings include lymphadenopathy (discrete, nonsuppurative, slightly painful, especially along the posterior cervical chain), transient bilateral upper lid edema (Hoagland sign), and splenomegaly (in up to 50% of patients). A maculopapular or occasionally petechial rash occurs in < 15% of patients unless ampicillin is given (in which case rash is seen in > 90%). Conjuctival hemorrhage (Figure 32–4), exudative pharyngitis, uvular edema, tonsillitis, or gingivitis may occur and soft palatal petechiae may be noted.

Other manifestations include hepatitis, cholestasis, gastritis, nervous system involvement in 1–5% (mononeuropathies and occasionally aseptic meningitis, encephalitis, cerebellitis, peripheral and optic neuritis, transverse myelitis, or Guillain-Barré syndrome), kidney disease (mostly interstitial nephritis), pneumonia, pleural involvement, and myocarditis. Vaginal ulcers are rare but may be present. Airway obstruction from lymph node enlargement, periarteritis, life-threatening thrombocytopenia, severe CNS
complications, and massive splenomegaly are all considered indications for hospitalization or close observation. Mesenteric adenitis may mimic an acute abdomen.

**B. Laboratory Findings**

In infectious mononucleosis an initial phase of granulocytopenia is followed within 1 week by lymphocytic leukocytosis (> 50% of all leukocytes) with atypical lymphocytes (larger than normal mature lymphocytes, staining more darkly, and showing vacuolated, foamy cytoplasm and dark nuclear chromatin) comprising >10% of the leukocyte count. Hemolytic anemia, with anti-I antibodies, occurs occasionally as does thrombocytopenia (at times marked).

The diagnosis of infectious mononucleosis is commonly made on the basis of characteristic manifestations and serologic evidence of infection (the heterophil sheep cell agglutination [HA] antibody tests or the correlated mononucleosis spot test [Monospot]). These tests usually become positive within 4 weeks after onset of illness and are specific but often not sensitive in early illness. Heterophil antibodies may be absent in young children and in as many as 20% adults. During acute illness, there is a rise and fall in immunoglobulin M (IgM) antibody to EB virus capsid antigen (VCA) and a rise in IgG antibody to VCA, which persists for life. Antibodies (IgG) to EBV nuclear antigen (EBNA) appear after 4 weeks of onset and also persist. Absence of IgG and IgM VCA or the presence of IgG EBNA should make one reconsider the diagnosis of acute EBV infection.

PCR for EBV DNA is useful in the evaluation of malignancies associated with EBV. For instance, detection of EBV DNA in cerebrospinal fluid shows a sensitivity of 90% and specificity of nearly 100% for the diagnosis of primary CNS lymphoma in patients with AIDS, and monitoring of quantitative EBV DNA levels (a "viral load") in blood may be useful in early detection of post-transplant lymphoproliferative disorder in high-risk patients. PCR analysis may also be helpful in monitoring disease and treatment response in primary CNS lymphoma and posttransplant lymphoproliferative disorder patients. Antibodies against ZEBRA (a replication protein) are produced in early infection and assays for these antibodies are commercially available.

**Differential Diagnosis**

CMV infection, toxoplasmosis, acute HIV infection, secondary syphilis, HHV-6, rubella, and drug hypersensitivity reactions may be indistinguishable from infectious mononucleosis due to EBV, but exudative pharyngitis is usually absent and the heterophil antibody tests are negative. With acute HIV infection, rash and mucocutaneous ulceration are common but atypical lymphocytosis is much less common. Heterophil-negative infectious mononucleosis with nonsignificant lymphocytosis (especially if rash or mucocutaneous ulcers are present) should prompt investigation for acute HIV infection. Heterophil-negative infectious mononucleosis with atypical lymphocytosis can be caused by CMV, toxoplasmosis and, on occasion, EBV itself. Mycoplasma infection may also present as pharyngitis, though lower respiratory symptoms usually predominate. A hypersensitivity syndrome induced by carbamazepine or phenytoin may mimic infectious mononucleosis.

The differential diagnosis of acute exudative pharyngitis includes diphtheria, gonococcal and streptococcal infections, and infections with adenovirus and herpes simplex. Head and neck soft tissue infections (pharyngeal and tonsillar abscesses) may occasionally be mistaken as the lymphadenopathy of mononucleosis.

**Complications**

Secondary bacterial pharyngitis can occur and is often streptococcal. Splenic rupture (0.5–1%) is a rare but dramatic complication, and a history of preceding trauma can be elicited in 50% of the cases. Acalculous cholecystitis, fulminant hepatitis with massive necrosis, pericarditis and myocarditis are also infrequent complications. Neurologic involvement—including transverse myelitis, encephalitis, and Guillain-Barré syndrome—is infrequent.

**Treatment**

**A. General Measures**

Over 95% of patients with acute EBV-associated infectious mononucleosis recover without specific antiviral therapy. Treatment is symptomatic with acetaminophen or other nonsteroidal anti-inflammatory drugs and warm saline throat irrigations or gargles three or four times daily. Acyclovir decreases viral shedding but shows no clinical benefit. Corticosteroid therapy, although widespread, is not recommended in uncomplicated cases; its use is reserved for impending airway obstruction from enlarged lymph nodes, hemolytic anemia, and severe thrombocytopenia. The value of corticosteroid therapy in impending splenic rupture, pericarditis, myocarditis, and nervous system involvement is less well defined. If a throat culture grows β-hemolytic streptococci, a 10-day course of penicillin or erythromycin is indicated. Ampicillin and amoxicillin are avoided because of the frequent association with rash.

**B. Treatment of Complications**

Hepatitis, myocarditis, and encephalitis are treated symptomatically. Rupture of the spleen requires splenectomy and is most often caused by deep palpation of the spleen or vigorous activity. Patients should avoid contact or collision sports for at least 4 weeks to decrease the risk of splenic rupture (even if splenomegaly is not detected by physical examination which can be insensitive).

**Prognosis**

In uncomplicated cases, fever disappears in 10 days and lymphadenopathy and splenomegaly in 4 weeks. The debility sometimes lingers for 2–3 months. Death is uncommon and is usually due to splenic rupture, hypersplenic phenomena (severe hemolytic anemia, thrombocytopenic purpura), or encephalitis.
4. Other Epstein–Barr Virus Syndromes

EBV viral antigens are found in > 90% of patients with endemic (African) Burkitt lymphoma and nasopharyngeal carcinoma (among whom quantified EBV DNA can be used to follow disease). Risk factors for Burkitt lymphoma include a history of malaria (which may decrease resistance to EBV infection) while risk factors for nasopharyngeal carcinoma include long-term heavy cigarette smoking and seropositive EBV serologies (VCA and deoxyribonuclease [DNase]). VCA-IgA in peripheral blood is a sensitive and specific predictor for nasopharyngeal carcinoma in endemic areas.

Chronic EBV infection is associated with aberrant cellular immunity (a low frequency of EBV-specific CD8 cells), an X-linked lymphoproliferative syndrome (Duncan disease), lymphomatoid granulomatosis, and a fatal T cell lymphoproliferative disorder in children.

EBV is an important cause of hemophagocytic lymphohistiocytosis among immunodeficient patients, B-cell lymphomas (such as primary CNS lymphoma in HIV-infected individuals), and posttransplant lymphoproliferative disorder. In fact, over 70% of posttransplant lymphoproliferative states are associated with EBV. EBV-naïve patients who receive a donor organ from an EBV-infected donor are at the highest-risk for the development of posttransplant lymphoproliferative disorder. Decreasing the iatrogenic immunosuppression, given to reduce graft rejection, is the highest-risk for the development of posttransplant lymphoproliferative disorder. Decreasing the iatrogenic immunosuppression, given to reduce graft rejection, is the highest-risk for the development of posttransplant lymphoproliferative disorder. Decreasing the iatrogenic immunosuppression, given to reduce graft rejection, is the highest-risk for the development of posttransplant lymphoproliferative disorder. Decreasing the iatrogenic immunosuppression, given to reduce graft rejection, is the highest-risk for the development of posttransplant lymphoproliferative disorder. Decreasing the iatrogenic immunosuppression, given to reduce graft rejection, is the highest-risk for the development of posttransplant lymphoproliferative disorder.

The efficacy of rituximab therapy can be often assessed by monitoring levels of EBV DNA load in the blood and, if indicated, CNS. Infusion of EBV-specific cytotoxic T cell lymphocytes (adoptive cell therapy) is also used but with a less established role.

Age is a major determinant of the type of tumor associated with EBV. T and NK cell lymphoma caused by chronic active EBV infections are more frequent in childhood while peripheral T cell lymphomas and diffuse large B cell lymphomas are more common in the elderly due to waning immunity. EBV is also associated with leiomyomas in children with AIDS and with nasal T cell lymphomas.

EBV is often implicated in the pathogenesis of a host of disorders from Hodgkin disease and gastric carcinoma to CNS demyelination, multiple sclerosis, Graves disease, histiocytic necrotizing lymphadenitis (Kikuchi-Fujimoto disease), chronic obstructive pulmonary disease (COPD), rheumatic diseases, and dental disorders (pulpitis and apical periodontitis). EBV was previously linked with the chronic fatigue syndrome but there is no persuasive evidence for an association, nor does there appear to be an association between chronic fatigue syndrome and xenotropic murine leukemia virus-related virus. Oral hairy leukoplakia and its association with EBV are discussed in Chapter 8.

5. Cytomegalovirus Disease

Most CMV infections are asymptomatic. After primary infection, the virus remains latent in most body cells. Seroprevalence in adults of Western developed countries is about 60–80% but is higher in developing countries. CMV seroprevalence increases with age, number of sexual partners, history of prior sexually transmitted infections, and low socioeconomic status. The virus can be isolated from a variety of tissues under nonpathogenic conditions. Transmission occurs through sexual contact, breastfeeding, blood products, or transplantation; it may also occur person-to-person (eg, day care centers) or be congenital. Serious disease occurs primarily in immunocompromised persons.

There are three recognizable clinical syndromes: (1) perinatal disease and CMV inclusion disease; (2) diseases in immunocompetent persons; and (3) diseases in immunocompromised persons. Congenital CMV infection is the most common congenital infection in developed countries (between 0.2% and 2% of all live births, with higher rates in

When to Admit
- Acute meningitis, encephalitis, or acute Guillain-Barré syndrome.
- Severe thrombocytopenia.
- Potential splenic rupture.

Airway obstruction from severe adenitis.
- Significant hemolysis.
- Pericarditis.
- Abdominal findings mimicking an acute abdomen.

underdeveloped areas and among lower socioeconomic groups). Transmission is much higher from mothers with primary disease than those with reactivation (40% vs 0.2–1.8%). About 10% of infected newborns will be symptomatic with CMV inclusion disease. In immunocompetent persons, acute CMV infection is the most common cause of the mononucleosis-like syndrome with negative heterophil antibodies. CMV appears to play a role in critically ill immunocompetent adults wherein it is reactivated and associated with prolonged hospitalization and death. Other syndromes associated with CMV and whose role in pathogenesis requires further elucidation include inflammatory bowel disease, atherosclerosis, cognitive decline, and breast cancer. In immunocompromised persons, tissue and bone marrow transplant patients are mainly at risk for a year after allograft transplantation (but especially during the first 100 days afterward) and in particular when graft-versus-host disease or CMV seropositivity, or both, are present in the donor and recipient. Depending on the serostatus of the donor and recipient, disease may present as primary infection or reactivation. The risk of CMV disease is proportionate to the intensity of immunosuppression. CMV itself is immunosuppressive. CMV may contribute to transplanted organ dysfunction, which often mimics organ rejection. CMV disease in HIV-infected patients (retinitis, serious gastrointestinal disease) occurs most prominently when the CD4 count is < 50 cells/mL. HAART reduces the frequency of retinitis and may reverse active disease. CMV retinitis may also develop after solid organ or bone marrow transplantation. CMV retinitis associated with intravitreal delivery of corticosteroids (injections or implants) or systemic anti-tumor necrosis factor antibodies is also described. Occasionally, CMV retinitis presents in immunocompetent persons. Serious gastrointestinal CMV disease also occurs after organ transplantation, cancer chemotherapy, or corticosteroid therapy. CMV may exist alongside other pathogens, such as Cryptosporidium, in up to 15% of patients with AIDS cholangiopathy. CMV pneumonitis occurs in transplant recipients (mainly bone marrow and lung) with a mortality rate up to 60–80%, and less often in AIDS patients. CMV pneumonitis in hematologic malignancies (eg, lymphoma) is increasingly reported. Neurologic CMV in patients with advanced AIDS is usually associated with disseminated CMV infection.

### Clinical Findings

#### A. Symptoms and Signs

1. **Perinatal disease and CMV inclusion disease**—CMV inclusion disease in infected newborns is characterized by jaundice, hepatosplenomegaly, thrombocytopenia, purpura, microcephaly, ventriculomegaly, focal encephalitis, mental retardation, and motor disability. Hearing loss develops in > 50% of infants who are symptomatic at birth. Most infected neonates are asymptomatic, but neurologic deficits may ensue later in life, including hearing loss in 15% and mental retardation in 10–20%. Perinatal infection acquired through breastfeeding or blood products typically shows a benign clinical course.

2. **Disease in immunocompetent persons**—Acute acquired CMV infection is characterized by fever, malaise, myalgias, arthralgias, and splenomegaly. Exudative pharyngitis or cervical lymphadenopathies are uncommon, but cutaneous rashes (including the typical maculopapular rash after exposure to ampicillin) are common. The mean duration of symptoms is 7–8 weeks. Complications include mucosal gastrointestinal damage, encephalitis, severe hepatitis, thrombocytopenia (on occasion, refractory), the Guillain-Barré syndrome, pericarditis, and myocarditis. The risk of Guillain-Barre syndrome developing after primary CMV infection is estimated to be 0.6–2.2 cases per 1000 primary infection, similar to that seen with Campylobacter jejuni infection. The mononucleosis-like syndrome due to CMV can also occur postsplenectomy, often years later and associated with a protracted fever, marked lymphocytosis, and impaired anti-CMV IgM response.

3. **Disease in immunocompromised persons**—Distinguishing between CMV infection (with evidence of CMV replication) and CMV disease (evidence for systemic symptoms or organ invasion) is important. In addition to patients infected with HIV, those who have undergone transplantation (solid organ or hematopoietic stem cell) show a wide spectrum of disease including gastrointestinal (including acute cholecystitis), renal, and CNS disease, as outlined above. CMV viral loads correlate with prognosis after transplantation.

   A. **CMV retinitis**—A funduscopic examination reveals neovascular, proliferative lesions (“pizza-pie” retinopathy). Immune restoration with HAART is associated with CMV vitritis and cystoid macular edema. Infants with CMV retinitis tend to have more macular than peripheral disease.

   B. **Gastrointestinal and hepatobiliary CMV**—Esophagitis presents with odynophagia. Gastritis can occasionally cause bleeding, and small bowel disease may mimic inflammatory bowel disease or may present as ulceration or perforation. Colonic CMV disease causes diarrhea, hematochezia, abdominal pain, fever, and weight loss and may mimic inflammatory bowel disease. CMV hepatitis commonly complicates liver transplantation and appears to be increased in those with hepatitis B or hepatitis C viral infection.

   C. **Respiratory CMV**—CMV pneumonitis is characterized by cough, dyspnea, and relatively little sputum production.

   D. **Neurologic CMV**—Neurologic syndromes associated with CMV include polyradiculopathy, transverse myelitis, ventriculomegaly (suspected with ependymitis), and focal encephalitis. These manifestations are more prominent in patients with advanced AIDS in whom the encephalitis has a subacute onset.

#### B. Laboratory Findings

1. **Mothers and newborns**—Pregnant women should be tested for IgM CMV antibodies every 3 months if an assay during the first trimester is seropositive. Congenital
CMV disease is confirmed by presence of the virus in amniotic fluid or an IgM assay from fetal blood. Amniocentesis is less reliable before 21 weeks of gestation (due to inadequate fetal urinary development and release into the amniotic fluid), but amniocentesis is attendant with greater risk when performed after 21 weeks of gestation. PCR assays of dried blood samples from newborns and micro-enzyme-linked immunosorbent assay (ELISA) on urine, saliva or blood specimens obtained during the first 3 weeks of life are used to diagnose congenital CMV infection.

2. Immunocompetent persons—The acute mononucleosis-like syndrome is characterized by initial leukopenia; within 1 week, it is followed by absolute lymphocytosis with atypical lymphocytes. Abnormal liver function tests are common in the first 2 weeks of the disease (often 2 weeks after the fever). Detection of CMV-specific IgM or a fourfold increase of specific IgG levels support the diagnosis of acute infection.

3. Immunocompromised persons—CMV retinitis is diagnosed on the basis of the characteristic ophthalmoscopic findings. In HIV-infected patients, negative CMV serologies lower the possibility of the diagnosis but do not eliminate it. Cultures alone are of little use in diagnosing AIDS-related CMV infections, since viral shedding of CMV is common. PCR analysis should be used to diagnose CNS infection since cultures are insensitive.

Detection of pp65 antigen in blood and determination of quantitative CMV antigenemia (“viral load”) by PCR are increasingly used in posttransplant patients for guidance on both treatment and prevention and should be interpreted in the context of clinical and pathologic findings, although full standardization of CMV viral loads is under development. The PCR is sensitive in predicting clinical disease. Quantitative PCR of bronchoalveolar lavage fluid seems to be useful for diagnosing CMV pneumonia.

Rapid shell-vial cultures for detection of early CMV antigens with fluorescent antibodies have largely replaced the conventional tube culture (for detection of cytopathic changes) since the time to positivity is greatly reduced (24–48 hours compared to weeks). Shell-vial cultures are more useful on bronchoalveolar lavage fluid than in routine blood monitoring.

A variety of false-positive immunologic assays occur in the setting of acute CMV infections, including positive rheumatoid factor, direct Coombs test, cryoglobulins, and speckled antinuclear antibody.

In gastrointestinal disease, CMV antigenemia is more specific than sensitive.

C. Imaging

The chest radiographic findings of CMV pneumonitis are consistent with interstitial pneumonia.

D. Biopsy

Tissue confirmation is especially useful in diagnosing CMV pneumonitis and CMV gastrointestinal disease; the diagnosis of colonic CMV disease is made by mucosal biopsy showing characteristic CMV histopathologic findings of intranuclear (“owl’s eye”) and intracytoplasmic inclusions.

▶ Treatment

Sight-threatening CMV retinitis (lesions close to the fovea or optic nerve head) is treated with ganciclovir induction therapy (5 mg/kg intravenously every 12 hours for 14–21 days) followed by maintenance therapy at lower doses (5 mg/kg intravenously daily). Sustained-release ganciclovir intraocular implants (always accompanied by systemic valganciclovir) are another option. In less severe retinal disease, valganciclovir (900 mg orally twice daily for 14–21 days followed by 900 mg/d maintenance) is preferred. Due to potential toxicities, foscarnet, cidofovir, and famciclovir are usually reserved for CMV infections that are resistant to ganciclovir. Combinations of ganciclovir and foscarnet are shown to be safe and effective in treating clinically resistant CMV retinitis. The role of HAART in reducing the need for CMV antiviral agents is essential. Other forms of CMV disease in AIDS are managed initially with intravenous ganciclovir and subsequently with oral valganciclovir; alternative agents (listed above) are used when resistance evolves.

The treatment of other systemic CMV infection (colitis, encephalitis, pneumonia) involves the use of the main antiviral agents used in CMV retinitis. The length of therapy depends on the state of immunosuppression, and secondary prophylaxis is typically maintained until immune restoration is present for at least 6 months. Prolonged prophylaxis may be necessary in other immunosuppressed patients, such as those receiving tumor necrosis factor (TNF) inhibitors.

For non-severe, posttransplant CMV disease, oral valganciclovir (900 mg twice daily) or intravenous ganciclovir (5 mg/kg every 12 hours) are the recommended first-line agents. Valganciclovir has been shown to be noninferior to intravenous ganciclovir-based therapy in solid organ transplant patients and is associated with less clinical resistance than ganciclovir. For severe CMV disease, intravenous ganciclovir remains the treatment of choice. Dosage adjustments of all medications are needed for kidney dysfunction. Reduction of immunosuppression should be attempted when possible (especially for muromonab, azathioprine, or mycophenolate mofetil). Treatment should be continued for at least 2 weeks until viral eradication is achieved. Two consecutive negative samples of CMV quantitative analysis testing or antigenemia based assay ensure viral clearance. Other agents that may be useful in resistant CMV infections include leflunomide, sirolimus-based therapy, and artesunate. Adoptive immunotherapy is also under study.

In pregnant women with primary CMV infection, passive immunization with hyperimmune globulin appears preliminarily to be effective in both treatment and prevention of fetal infection, but controlled clinical trials are lacking. While CMV immunoglobulin is also used in the
treatment of CMV pneumonia in stem cell transplant recipients, its efficacy is not completely established.

▶ Prevention

A CMV glycoprotein B with MF59 adjuvant vaccine is currently under development. Phase 2 studies show vaccine efficacy of 50% in preventing congenital disease as well as increased antibody titers compared to placebo in seronegative and seropositive transplant recipients and in a population of CMV infected women.

HAART is effective in preventing CMV infections in HIV-infected patients. Use of leukocyte-depleted blood products effectively reduces the incidence of CMV disease in patients who have undergone transplantation. Prophylactic and preemptive strategies (eg, antiviral agents only when antigen detection or PCR assays show evidence of active CMV replication) are effective in preventing disease in the early transplantation period but are associated with a risk of a late-onset form of the disease after the prophylaxis is discontinued. The appropriate management of transplant patients is based on the serostatus of the donor and the recipient. All effective anti-CMV agents can serve as prophylactic agents for CMV-seropositive transplants or for CMV-seronegative recipients of CMV-positive organ transplants. A recent meta-analysis shows that valganciclovir prophylaxis at a lower dose (450 mg orally twice daily vs 900 mg orally twice daily) is equally effective in solid organ transplant patients with less risk of leukopenia and rejection. CMV immune globulin may also be useful in reducing the incidence of bronchiolitis obliterans in the bone marrow transplant population and is used in some centers as part of the prophylaxis in kidney, liver, and lung transplantation patients. CMV immune globulin as prophylaxis is not recommended in hematopoietic stem cell transplant recipients.

Withdrawal of infected children from day care centers, reduction of patient contact by health care workers, screening for women of childbearing age, or restrictions to breastfeeding are not recommended because the virus is ubiquitous.

▶ When to Refer

- Neonatal infections consistent with CMV inclusion disease.
- AIDS patients with retinitis, esophagitis, colitis, hepato-biliary disease, or encephalitis.
- Organ and hematopoietic stem cell transplants with suspected reactivation CMV.

▶ When to Admit

- Risk of colonic perforation.
- Evaluation of unexplained, advancing encephalopathy.
- Biopsy of tissues in the differential diagnosis of transplant rejection vs infection.
- Initiation of treatment with intravenous anti-CMV agents.

6. Human Herpesviruses 6, 7, & 8

HHV-6 is a B cell lymphotropic virus that is the principal cause of exanthema subitum (roseola infantum, sixth disease). Primary HHV-6 infection occurs most commonly in children under 2 years of age and is a major cause of infantile febrile seizures. HHV-6 is also associated with encephalitis (symptoms may include insomnia, seizures, and hallucinations) and with acute liver failure. Primary infection in immunocompetent adults is rare and can produce a monoclonal antibody response. Reactivation of HHV-6 in immunocompetent adults is rare and can present as encephalitis. Imaging studies in HHV-6 encephalitis typically show lesions in the hippocampus, amygdala, and limbic structures.

Infection during pregnancy and congenital transmission is recognized. Most cases of reactivation, however, occur in immunocompromised persons. Reactivation is associated with graft rejection, graft-versus-host disease, and bone marrow suppression in transplant patients and with encephalitis and pneumonitis in AIDS patients and in recipients of hematopoietic cell transplants. HHV-6 is on occasion also associated with drug-induced hypersensitivity syndromes that may evolve into diabetes mellitus. The roles of HHV-6 in multiple sclerosis, chronic fatigue syndrome, certain malignancies, myocarditis and progressive multifocal leukoencephalopathy remain unproven. HHV-6 may cause fulminant hepatic failure and acute decompensation of chronic liver disease in children. Purpura fulminans is reported rarely with HHV-6 infection. Recent studies suggest that HHV-6 can cause corneal inflammation.
HHV-7 is synergistic with CMV in kidney transplant recipients. The membrane glycoprotein CD4 is involved in HHV-7 recognition, but a clinical interaction between HHV-7 and HIV is not established.

HHV-8 is associated with Kaposi sarcoma, multicentric Castleman disease, and primary effusion (body cavity) lymphoma. HHV-8 infection is endemic in Africa; transmission seems to be primarily horizontal in childhood from intrafamilial contacts and continues through adulthood possibly by nonsexual routes. An association between HHV-8 and the development of systemic lupus erythematosus is under study. See Chapter 31 for pathogenesis and management.

MAJOR VACCINE-PREVENTABLE VIRAL INFECTIONS

1. Measles

**ESSENTIALS OF DIAGNOSIS**

- Exposure 10–14 days before onset in an unvaccinated patient.
- Prodrome of fever, coryza, cough, conjunctivitis, malaise, irritability, photophobia, Koplik spots.
- Rash: brick-red, irregular, maculopapular; onset 3–4 days after onset of prodrome; begins on the face and proceeds “downward and outward,” affecting the palms and soles last.
- Leukopenia.

**General Considerations**

Measles is a reportable acute systemic paramyxoviral infection transmitted by inhalation of infective droplets. It is a major worldwide cause of pediatric morbidity and mortality, although vaccination programs successfully reduced this number from nearly 750,000 deaths in 2000 to an estimated 164,000 in 2008. The case numbers increased in 2011 with over 28,000 cases reported in Europe (high risk groups include the Roma, travelers, immigrants, and Orthodox Jews) with the largest number from France. The 214 US measles cases as of October 2011 included 73 (34%) importations (France and India were the leading source countries).

Illness confers permanent immunity. It is highly contagious and communicability is greatest during the preeruptive and catarrhal stages but continues as long as the rash remains. Despite high community vaccination coverage, rising rates of intentional undervaccination lead to sporadic outbreaks among clusters of intentionally undervaccinated children and can undermine measles elimination programs. Therefore, laboratory testing and confirmation of suspected measles infection is especially important in countries that report the elimination of measles. Sporadic outbreaks of the disease in adults, adolescents, and unvaccinated preschool children in dense urban areas, and sporting event participants emphasize the need for specific recommendations concerning prevention (see below).

In the United States, measles was declared eliminated in 2000. The few reported cases since then are largely imported and geographically dispersed, and the associated isolates fail to show a recurrent strain. Immigrants and refugees can show serosusceptibility rates to measles in excess of 35%.

**Clinical Findings**

**A. Symptoms and Signs**

Fever is often as high as 40–40.6 °C. It persists through the prodrome and early rash (about 5–7 days) (Table 32–2). Malaise may be marked. Coryza (nasal obstruction, sneezing, and sore throat) resembles that seen with upper respiratory infections. Cough is persistent and nonproductive. Conjunctivitis manifests as redness, swelling, photophobia, and discharge. These symptoms intensify over 2–4 days before onset of the rash and peak on the first day of the rash.

Koplik spots (small, irregular, and red with whitish center on the mucous membranes) are pathognomonic of measles. They appear about 2 days before the rash and last 1–4 days as tiny “table salt crystals” in the buccal mucosa opposite the molars and vaginal membranes. The rash usually appears on the face and behind the ears 4 days after the onset of symptoms. The initial lesions are pinhead-sized papules that coalesce to form a brick-red, irregular, blotchy maculopapular rash. In severe cases, the rash coalesces to form a nearly uniform erythema in some areas. The rash next appears on the trunk, followed by the extremities, including the palms (25–50% of those infected) and soles. The rash last for 3–7 days and fades in the same manner it appeared. Hyperpigmentation remains in fair-skinned individuals and the last cases. Slight desquamation may follow. Other findings in measles include pharyngeal erythema, tonsillar yellowish exudate, coating of the tongue in the center with a red tip and margins, moderate generalized lymphadenopathy and, at times, splenomegaly.

**Atypical measles** is a syndrome occurring in adults who received inactivated measles vaccine (1963–1968) or who received live measles vaccine before age 12 months and as a result developed hypersensitivity rather than protective immunity. Infection later in life with wild measles
virus can lead to a potentially fatal illness with high fever; unusual rashes (papular, hemorrhagic), most prominent on the extremities, without Koplik spots; headache; arthralgias; hepatitis; a high rate of pneumonitis, and sometimes pleural effusions. Atypical measles cases show unusually high hemagglutinin-inhibition titers. Measles may be distinctive in HIV-infected individuals, with higher rates of pneumonitis, higher mortality, prolonged viral shedding, and higher vaccine failure rates. Measles during pregnancy is not known to cause congenital abnormalities of the fetus. It is, however, associated with spontaneous abortion and premature delivery and can cause severe disease in the mother. Although measles does not always develop in the offspring of mothers with the disease, it can be severe when it does. It is recommended that infants born to such mothers be passively immunized with immunoglobulin at birth.

The virologic clearance of measles can take months.

B. Laboratory Findings

Leukopenia is usually present unless secondary bacterial complications exist. A lymphocyte count under 2000/mcL is a poor prognostic sign. Thrombocytopenia is common. Proteinuria is often observed. Although technically difficult, virus can be cultured from nasopharyngeal washings and from blood. Detection of IgM measles antibodies with ELISA or a fourfold rise in serum hemagglutination inhibition antibody supports the diagnosis. Fluorescent antibody staining of respiratory or urinary epithelial cells can also confirm the diagnosis.

IgM assays can be falsely negative the first few days of infection and falsely positive in the presence of rheumatoid factor or with acute rubella, erythrovirus (parvovirus) B19, or HHV-6 infection. White reverse transcriptase-PCR techniques, typically available in research settings, can help establish a diagnosis; the persistence of the virus for months after an acute infection can lead to false positive results.

Differential Diagnosis

Measles is usually diagnosed clinically but may be mistaken for other exanthematous infections (see Table 32–2). Frequent difficulty in establishing a diagnosis suggests that measles may be more prevalent than is recognized.

Complications

A. Central Nervous System

Postinfectious encephalomyelitis occurs in about 0.05–0.1% of cases. Higher rates of encephalitis occur in adolescents and adults than in school-aged children. Its onset is usually 3–7 days after the rash. Vomiting, convulsions, coma, and diverse, severe neurologic symptoms and signs may develop. Treatment is symptomatic and supportive. Virus is usually not found in the CNS, though demyelination is prominent. There is an appreciable mortality (10–20%) and morbidity (33% of survivors are left with neurologic deficit).

A similar form, “inclusion body encephalitis,” occurs months after exposure. This complication is reported to occur after measles vaccination in patients with inadequate cellular immunity but is associated with isolation of the measles virus.

Subacute sclerosing panencephalitis (SSPE) is a very late CNS complication (5–15 years after infection; the measles virus acts as a “slow virus” to produce degenerative CNS disease years after the initial infection. SSPE is rare (1:100,000 cases of measles) and occurs more often when measles develops early in life among males who live in rural environments. SSPE very rarely develops in adults.

Measles virus can opportunistically invade the CNS. An acute progressive encephalitis (subacute measles encephalitis), characterized by seizures, neurologic deficits, and often progressive stupor and death, can occur among immunosuppressed patients. Treatment is supportive, withholding immunosuppressive chemotherapy when feasible. Interferon and ribavirin are variably successful.

B. Respiratory Tract Disease

Early in the course of the disease, bronchopneumonia or bronchiolitis due to the measles virus may occur in up to 5% of patients and result in serious respiratory difficulties. Bronchiectasis may occur in up to a quarter of non-vaccinated children. Pneumonia occurring with or without an evanescent rash is seen in atypical measles.

C. Secondary Bacterial Infections

Immediately following measles, secondary bacterial infection, particularly cervical adenitis, otitis media (the most common complication), and pneumonia, occurs in about 15% of patients.

D. Immune Reactivity

Measles produces temporary anergy to cell-mediated skin tests.

E. Gastroenteritis

Diarrhea and protein-losing enteropathy (prodromal rectal Koplik spots may be seen) are significant complications among malnourished children.

F. Other Complications

Other complications include conjunctivitis, keratitis, and otosclerosis.

Treatment

A. General Measures

The patient should be isolated for the week following onset of rash and kept at bed rest until afebrile. Treatment is symptomatic including antipyretics and fluids as needed. Vitamin A, 200,000 units/d orally for 2 days (the benefit being maintenance of gastrointestinal and respiratory epithelial mucosa), reduces pediatric morbidity (diarrhea, night blindness, xerophthalmia) and measles-associated mortality for infants between 6 months and 5 years of age,
Measles virus is susceptible to ribavirin in vitro and has been used in selected severe cases of pneumonitis (35 mg/kg/d intravenously in three divided doses for 2 days, followed by 20 mg/kg/d intravenously in three divided doses for 5 days).

B. Treatment of Complications

Secondary bacterial infections, including pneumonia, are treated with appropriate antibacterial antibiotics. Postmeasles encephalitis, including SSPE, can be managed only symptomatically.

Repeated studies fail to show an association between vaccination and autism. The prevalence of asthma-like diseases in childhood appears to be reduced among vaccinated children. Some data implicate the measles virus in the pathogenesis of rheumatoid arthritis.

Prognosis

Between 1999 and 2005, measles mortality rate was reduced an estimated 60%. In the last decade, the case-fatality rate in the United States stayed around 3 per 1000 reported cases, with deaths principally due to encephalitis (15% mortality rate) and secondary bacterial pneumonia. Deaths in the developing world are mainly related to diarrhea and protein-losing enteropathy.

Prevention

In the United States, children receive their first vaccine dose at 12–15 months and a second at age 4–6 years prior to entry into school. Combination measles-mumps-rubella-varicella vaccines (MMRV) can be used in place of the traditional measles, mumps, and rubella (MMR) vaccine. Recent outbreak data suggest that the efficacy of the vaccine persists longer if the first vaccination is given at a later age (eg, 15 months). The evidence is not convincing that routine anthelmintic treatment affects the immune response to childhood vaccination.

American students beyond high school and medical staff starting employment require documentation of the above vaccination schedule or must show serologic evidence of immunity if they were born after 1956. For individuals born before 1957, herd immunity is assumed. Health care workers, immigrants, and refugees should be screened and vaccinated if necessary regardless of date of birth. International travelers (if immunocompetent and born after 1956) to the developing world and teachers should receive booster doses of vaccination.

At 6 months of age, more than 99% of infants of vaccinated women and 95% of infants of naturally immune women lose maternal antibodies. Therefore, in outbreaks that include infants under 1 year of age, initial vaccination may be given at 6 months, with repeat at 15 months. When outbreaks take place in day care centers, K–12 institutions, or colleges and universities, revaccination is probably indicated for all, in particular for students and their siblings born after 1956 who do not have documentation of immunity as defined above. Susceptible personnel who were exposed should be isolated from patient contact between the fifth and the twenty-first day after exposure regardless of whether they were vaccinated or given immune globulin. If measles develops in these persons, they should be isolated from patient contact until 7 days after the rash develops.

When susceptible individuals are exposed to measles, live virus vaccine can prevent disease if given within 5 days of exposure. In addition, immune globulin (0.25 mL/kg [0.11 mL/lb] body weight) can be injected intramuscularly for prevention or modification of clinical illness if given within 6 days after exposure. This must be followed by active immunization with live measles vaccine 3 months later. Vaccination of all immunocompetent persons born after 1956 who travel to the developing world is important. In the developing world, the use of a second vaccine dose is an important aspect of achieving control of measles in the community.

Pregnant women and immunosuppressed persons should not receive this vaccine. Exception to this contraindication is asymptomatic HIV-infected patients, including children, who have not shown adverse effects from measles vaccination. In asymptomatic HIV-infected children, vaccination improves survival after measles, and HAART therapy is associated with an improved vaccine response. Repeat vaccination may be necessary in HIV-infected children after immune restoration. Immune globulin should be administered within 6 days of exposure for postexposure prophylaxis in any high-risk person exposed to measles. Such high-risk persons include children with malignancy and patients with AIDS who are at risk for developing severe or fatal disease.

Severe allergic reactions including anaphylaxis to the MMR vaccine are rare, though fever and rash appear to occur slightly more often among female recipients. Quadrivalent MMRV vaccine is associated with an increased risk of seizures that appears to be age-related; the risk is highest when MMRV is given to infants under 15 months of age. An aerosolized measles vaccine remains under study. Future vaccines for a variety of infectious agents may utilize measles vectors, thereby augmenting immunity to measles. Rare cases of post-immunization encephalitis represent a form of acute disseminated encephalomyelitis (which can occur after many other vaccines including rabies, DPT, smallpox, and hepatitis B virus vaccinations).

When to Refer

- Any suspect cases should be reported to public health authorities.
- HIV infection.
- Pregnancy.

When to Admit

- Meningitis, encephalitis, or myelitis.
- Severe pneumonia.
- Diarrhea that significantly compromises fluid or electrolyte status.
2. Mumps

**ESSENTIALS OF DIAGNOSIS**

- Exposure 14–21 days before onset.
- Painful, swollen salivary glands, usually parotid.
- Frequent involvement of testes, pancreas, and meninges in unvaccinated individuals.

**General Considerations**

Mumps is a paramyxoviral disease spread by respiratory droplets. Children are the age group most affected, although in some outbreaks, patients are in the late second or early third decades of life. Mumps can spread rapidly in congregate settings, such as colleges and schools. The incidence is highest in spring. The incubation period is 14–21 days (average, 18 days). Infectivity occurs via saliva and urine and precedes the symptoms by about 1 day and is maximal for 3 days, although it may last a week. Up to one-third of affected individuals have subclinical infection. In 2006, an outbreak of mumps in the United States occurred and involved over 6000 persons; 85% of these cases were reported from eight Midwestern states. More recent mumps outbreaks involved 1521 cases at a summer camp in New York (2009) and 134 cases among mostly undervaccinated boys in Ontario (2010). In recent seroprevalence studies of mumps antibody, the highest rates were seen in US-born Americans of African and Hispanic (Mexican-born) ancestry, reflecting perhaps immunity associated with natural infection.

**Clinical Findings**

**A. Symptoms and Signs**

Mumps is more serious in adults than in children. Parotid tenderness and overlying facial edema (Figure 32–5) are the most common physical findings and typically develop within 48 hours of the prodromal symptoms. Usually, one parotid gland enlarges before the other, but unilateral parotitis alone occurs in 25% of patients. The orifice of Stensen duct may be red and swollen. Trismus may result from parotitis. The parotid glands return to normal within a week. Involvement of other salivary glands (submaxillary and sublingual) occurs in 10% of cases.

Fever and malaise are variable but often minimal in young children. High fever accompanies meningitis or orchitis. Neck stiffness, headache, and lethargy suggest meningitis. Testicular swelling and tenderness (unilateral in 75% of cases) denote orchitis; the testes are the most common extrasalivary site of disease in adults. Orchitis develops 7–10 days after the onset of parotitis in about 25–40% of postpubertal men, but sterility is rare. Acute hormonal disturbances are prevalent, including decreased levels of testosterone and inhibin B with low or normal levels of gonadotropins in up to 35% cases with mumps orchitis. Upper abdominal pain, nausea, and vomiting suggest pancreatitis. Mumps is the leading cause of pancreatitis in children. Lower abdominal pain and ovarian enlargement suggest oophoritis (which occurs in 5% of postpubertal women, usually unilateral); it is a difficult diagnosis to establish.

**B. Laboratory Findings**

Mild leukopenia with relative lymphocytosis may be present. Serum amylase usually reflects salivary gland involvement rather than pancreatitis. Lymphocytic pleocytosis and hypoglycemia of the cerebrospinal fluid in meningitis may be asymptomatic. Mild kidney function abnormalities are found in up to 60% of patients.

Characteristic clinical picture is usually sufficient for diagnosis. An elevated serum IgM is considered diagnostic.
and a repeat test 2–3 weeks after the onset of symptoms is recommended if the first assay is negative due to a delay in IgM rise, especially in vaccinated persons. A fourfold rise in complement-fixing antibodies to mumps virus in paired serum IgG also confirms infection. Confirmatory diagnosis of mumps is also made by isolating the virus preferably from a swab of the duct of the parotid or other affected salivary gland. The virus can also be isolated from cerebrospinal fluid early in the course of aseptic meningitis. Isolation from urine is no longer advised. Nucleic acid amplification techniques are more sensitive than viral cultures but their availability is limited.

**Differential Diagnosis**

Swelling of the parotid gland may be due to calculi in the parotid ducts, tumors, or cysts, or to a reaction to iodides. Other causes include starch ingestion, sarcoidosis, cirrhosis, diabetes, bulimia, pilocarpine usage, and Sjögren syndrome. Parotitis may be produced by pyogenic organisms (e.g., S. aureus, gram-negative organisms), particularly in debilitated individuals with poor oral intake, drug reaction (phenothiazines, propylthiouracil), and other viruses (influenza A, parainfluenza, EBV infection, coxsackieviruses, adenoviruses, HHV-6). Swelling of the parotid gland must be differentiated from inflammation of the lymph nodes located more posteriorly and inferiorly than the parotid gland.

**Complications**

Other manifestations of the disease are less common and usually follow parotitis but may precede it or occur without salivary gland involvement. Such manifestations include meningitis (30%), orchitis (which on rare occasion leads to priapism or testicular infarction), pancreatitis (usually mild), oophoritis, thyroiditis, neuritis, hepatitis, myocarditis, thrombocytopenia, migratory arthralgias (noted infrequently among adults and rarely in children), and nephritis. Mumps has also been associated with cases of endocardial fibroelastosis.

Rare neurologic complications include encephalitis, Guillain-Barré syndrome, cerebellar ataxia, facial palsy, and transverse myelitis. Encephalitis is associated with cerebral edema, serious neurologic manifestations, and sometimes death. Deafness from eighth nerve neuritis develops in about 0.1%; it is typically unilateral, severe, and permanent.

**Treatment**

**A. General Measures**

The patient should be isolated until swelling subsides (about 9 days from onset) and kept on bed rest while febrile. Treatment is symptomatic. Topical compresses may relieve parotid discomfort. Some clinicians advocate intravenous immunoglobulin (IVIG) for complicated disease (e.g., thrombocytopenia) although its definitive role is unproven.

**B. Management of Complications**

1. **Aseptic meningitis**—The treatment is symptomatic. The management of encephalitis requires attention to cerebral edema, the airway, and vital functions.

2. **Epididymo-orchitis**—The scrotum should be supported with a suspensor or toweling “bridge” and ice bags applied. Incision of the tunica may be necessary in severe cases. Pain can be relieved with opioids, or by injecting the spermatic cord at the external inguinal ring with 10–20 mL of 1% procaine solution. The merit of hydrocortisone sodium succinate (100 mg intravenously, followed by 20 mg orally every 6 hours for 2 or 3 days) in reducing inflammation is not firmly established. Interferon alfa-2b may be useful in preventing testicular atrophy.

3. **Pancreatitis**—Symptomatic treatment should be provided, with emphasis on parenteral hydration.

**Prognosis**

The entire course of mumps rarely exceeds 2 weeks. Rare fatalities are usually due to encephalitis.

**Prevention**

Mumps live virus vaccine is safe and effective (there is some variability among vaccines, the Jeryl Lynn strain being highly effective, the Urbane intermediate, the Rubini less so) with long lasting immunity. It is recommended for routine immunization for children over age 1 year, either alone or in combination with other virus vaccines (e.g., in the MMR vaccine or as a quadrivalent vaccine with varicella). A second dose is recommended for children (ages 4–6 years) before starting school. (In recent outbreaks from Canada and Scotland, cases disproportionately included those who received only one dose of the vaccine.) Two doses of the vaccine should also be considered for high-risk individuals (e.g., health care workers) born before 1957 and without evidence of immunity. There are no known cases of long-term sequelae associated with mumps vaccination and the currently used mumps strain (Jeryl Lynn) shows the lowest associated incidence of post vaccine aseptic meningitis (from 1 in 150,000 to 1 in 1.8 million). This vaccine is less effective in epidemic settings. Reactions are reviewed in the measles section. It should not be given to pregnant women or to immunocompromised individuals, though the vaccine has been given to asymptomatic HIV-infected individuals without adverse sequelae, especially when the individuals are taking HAART. In the developed world, persons in whom mumps develops are less likely to have received a second vaccine dose. The mumps skin tests are less reliable than serum neutralization titers in determining immunity.

**When to Refer**

Any suspect cases should be reported to public health authorities.
### 3. Poliomyelitis

#### ESSENTIALS OF DIAGNOSIS

- Incubation period 9–12 days from exposure.
- Muscle weakness, headache, stiff neck, fever, nausea and vomiting, sore throat.
- Lower motor neuron lesion (flaccid paralysis) with decreased deep tendon reflexes and muscle wasting.
- Cerebrospinal fluid shows lymphocytic pleocytosis but rarely > 500/mL.

#### General Considerations

Poliomyelitis virus, an enterovirus, is present in throat washings and stools (excretion may last for weeks after infection). It is highly contagious through fecal–oral route, especially during the first week of infection. By 2005, because of global vaccination efforts, indigenous transmission of wild poliovirus (WPV) types 1 and 3 were eliminated from all but four countries (Afghanistan, India, Nigeria, and Pakistan) and no cases of WPV type 2 were reported since 1999, although a case was reported in 2011 of a woman with combined variable immunodeficiency who acquired type 2 poliomyelitis in Minnesota nearly 12 years after her child was given the oral vaccination. As of October 2011, a total of 467 cases of WPV infection were reported (down from 350,000 in 1988) from 11 countries with 47% of cases in endemic countries of Afghanistan, India, Nigeria, and Pakistan, with reactivation of the outbreak in the Democratic Republic of the Congo and Chad, and new outbreaks in the Central African Republic, China, Mali, Kenya, Guinea, Cote d’Ivoire, and Nigeria. India is down to a single case this year. The largest number of cases is being reported currently from Pakistan, Chad, and the Democratic Republic of the Congo. The last major outbreak in the Western Hemisphere occurred in Hispaniola (Haiti and the Dominican Republic) from 2000 to 2001. An ongoing outbreak of type 2 VDPV in Nigeria is reportedly the largest to date and is unique in occurring in the presence of extensive transmission of indigenous type 1 and 3 WPV.

#### Clinical Findings

##### A. Symptoms and Signs

At least 95% of infections are asymptomatic, but in those who become ill, manifestations include abortive poliomyelitis (minor illness), nonparalytic poliomyelitis, and paralytic poliomyelitis.

1. **Abortive poliomyelitis (minor illness)**—Such minor illness occurs in 4–8% of infections and the symptoms are fever, headache, vomiting, diarrhea, constipation, and sore throat lasting 2–3 days. This entity is suspected clinically only during an epidemic.

2. **Nonparalytic poliomyelitis**—In addition to the above symptoms, signs of meningeal irritation and muscle spasm occur in the absence of frank paralysis. This disease is indistinguishable from aseptic meningitis caused by other viruses.

3. **Paralytic poliomyelitis**—Paralytic poliomyelitis represents 0.1% of all poliomyelitis cases (the incidence is higher when infections are acquired later in life). Paralysis may occur at any time during the febrile period. Tremors, muscle weakness, constipation, and ileus may appear. Paralytic poliomyelitis is divided into two forms, which may coexist: (1) **spinal poliomyelitis**, with involvement of the muscles innervated by the spinal nerves, and (2) **bulbar poliomyelitis**, with weakness of the muscles supplied by the cranial nerves (especially nerves IX and X) and of the respiratory and vasomotor centers.

In spinal poliomyelitis, paralysis of the shoulder girdle often precedes intercostal and diaphragmatic paralysis, which leads to diminished chest expansion and decreased vital capacity. The paralysis occurs over 2–3 days, is flaccid, has an asymmetric distribution, and affects the proximal muscles of the lower extremities more frequently. Sensory loss is very rare.

In bulbar poliomyelitis, symptoms include diplopia (uncommonly), facial weakness, dysphagia, dysphonia, nasal voice, weakness of the sternocleidomastoid and trapezoid muscles, difficulty in chewing, inability to swallow or expel saliva, and regurgitation of fluids through the nose. The most life-threatening aspect of bulbar poliomyelitis is respiratory paralysis. Lethargy or coma may be due to hypoxia, most often from hypoventilation. Vasomotor disturbances in blood pressure and heart rate may occur.
B. Laboratory Findings

The peripheral white blood cell count may be normal or mildly elevated. Cerebrospinal fluid pressure and protein are normal or slightly increased. Glucose is not decreased. White blood cells usually number < 500/mcL and are principally lymphocytes after the first 24 hours. Cerebrospinal fluid is normal in 5% of patients. The virus may be recovered from throat washings (early) and stools (early and late). Neutralizing and complement-fixing antibodies appear during the first or second week of illness. Serologic testing cannot distinguish between wild-type and vaccine-related virus infections.

Differential Diagnosis

Nonparalytic poliomyelitis is similar to other forms of enteroviral meningitis; the distinction is made serologically. Acute flaccid paralysis is the term used in the developing world for the variety of neurologic illnesses that both include and mimic poliomyelitis. Acute flaccid paralysis due to poliomyelitis is distinguished by the greater frequency of fever and asymmetric neurologic signs. Acute inflammatory polyneuritis (Guillain-Barré syndrome), Japanese B virus encephalitis, West Nile virus infection, and tick paralysis may resemble poliomyelitis. In Guillain-Barré syndrome (see Chapter 24), the weakness is more symmetric and ascending in most cases, but the Miller Fisher variant is quite similar to bulbar polio. Paresthesias are uncommon in poliomyelitis but common in Guillain-Barré syndrome. The cerebrospinal fluid usually has high protein content but normal cell count in Guillain-Barré syndrome.

Complications

Urinary tract infection, atelectasis, pneumonia, myocarditis, paralytic ileus, gastric dilatation, and pulmonary edema may occur. Respiratory failure may be a result of paralysis of respiratory muscles, airway obstruction from involvement of cranial nerve nuclei, or lesions of the respiratory center.

Treatment

In the acute phase of paralytic poliomyelitis patients should be hospitalized. Strict bed rest in the first few days of illness reduces the rate of paralysis. Comfortable but rotating positions should be maintained in a "polio bed": firm mattress, footboard, sponge rubber pads or rolls, sandbags, and light splints. Intensive physiotherapy may help recover some motor function with paralysis. Fecal impaction and urinary retention (especially with paraplegia) are managed appropriately. In cases of respiratory weakness or paralysis, intensive care is needed. Attention to psychological disorders in long-standing disease is also important. The antiviral pleconaril shows no clear benefit in cases of polio meningoencephalitis.

Prognosis

During the febrile period, paralysis may develop or progress. Mild weakness of small muscles is more likely to regress than severe weakness of large muscles. Bulbar poliomyelitis carries a mortality rate of up to 50%. Long-term sequelae include pain, weakness, fatigue, and obesity, factors often worsened by age and comorbidities. When new muscle weakness and pain develop and progress slowly years after recovery from acute paralytic poliomyelitis, the entity is called postpoliomyelitis syndrome. This syndrome presents with signs of chronic and new denervation, is associated with increasing dysfunction of surviving motor neurons, and is not infectious in origin; patients do not shed the virus. Immune modulators, such as prednisone, interferon, and IVIG, do not show any clear benefits in the treatment of postpoliomyelitis syndrome.

Prevention

Given the epidemiologic distribution of poliomyelitis and the continued concern about vaccine-associated disease (estimated in 1:750,000 recipients) with the trivalent oral live poliovirus vaccine (OPV), the inactive (Salk) parenteral vaccination is currently used in the United States for all four recommended doses (at ages 2 months, 4 months, 6–18 months, and at 4–6 years). Inactivated vaccine is also routinely used elsewhere in the developed world. Oral vaccines are limited to usage for outbreak control, travel to endemic areas within the ensuing month, and protection of children whose parents do not comply with the recommended number of immunizations. The advantages of oral vaccination are the ease of administration, low cost, effective local gastrointestinal and circulating immunity, and herd immunity.

Routine immunization of adults in the United States is no longer recommended because of the low incidence of the disease. Exceptions include adults not vaccinated within the prior decade who are exposed to poliomyelitis or who plan to travel to endemic areas (mentioned above). Vaccination should also be considered for adults engaged in high-risk activities (eg, laboratory workers handling stools). Such adults should be given inactivated poliomyelitis vaccine (Salk) as should immunodeficient or immunosuppressed individuals and members of their households.

In the developing world, three doses of OPV seem sufficient for adequate immunization and the interval between doses should probably be > 1 month (because of interference from enteric pathogens). Intramuscular injections should be routinely avoided during the month following oral poliomyelitis vaccination to prevent provocation paralysis. Clinical studies suggest that rotavirus and OPV can be given concomitantly. Ancillary useful control measures ("supplementary immunization activities") in polioendemic countries include national immunization days (mass campaigns in which all children are vaccinated twice, 4–6 weeks apart, regardless of vaccine history); cross-border vaccination activities; surveillance for acute flaccid paralysis, an indicator for poliomyelitis; and aggressive
outbreak responses as well as intensified immunization activities in countries impacted by armed conflicts.

VPDV cases with the oral Sabin vaccination are due to mutations leading to neurovirulence. Such cases serve as a reminder of the need to maintain high levels of immunization coverage even in the absence of overt disease. An immunogenic monovalent type 1 oral vaccine (several times more effective than the trivalent oral vaccine) is successfully used in India, Egypt, and Nigeria. Cost and administrative considerations along with a need for effective herd immunity remain major reasons the oral Sabin is still administered.

There is no epidemiologic evidence to implicate poliomyelitis vaccination as a cause for recurrent worsening wheezing or eczema in childhood.

When to Refer

- Neurologic compromise.
- Any suspicious cases should be referred to public health authorities.

4. Rubella

ESSENTIALS OF DIAGNOSIS

- Exposure 14–21 days before onset.
- Arthralgia, particularly in young women.
- No prodrome in children, mild prodrome in adults; mild symptoms (fever, malaise, coryza) coinciding with eruption.
- Posterior cervical and postauricular lymphadenopathy 5–10 days before rash.
- Fine maculopapular rash of 3 days duration; face to trunk to extremities.
- Leukopenia, thrombocytopenia.

General Considerations

Rubella is a systemic disease caused by a togavirus transmitted by inhalation of infective droplets. It is only moderately communicable. One attack usually confers permanent immunity but reinfection is possible, albeit rarely. The incubation period is 14–21 days (average, 16 days). The disease is transmissible from 1 week before the rash appears until 15 days afterward.

The clinical picture of rubella is difficult to distinguish from other viral illnesses such as infectious mononucleosis, measles, echovirus infections, and coxsackievirus infections; however, arthritis is more prominent in rubella. Surveillance of female military recruits suggests that serologic protection against rubella, measles, and mumps are inadequate. The rubella case load decreased from 670,894 cases in 2000 to 121,344 cases in 2009 with reports of disease from 167 nations. Rubella containing vaccine is available in 130 nations. In the United States, rubella is not endemic since 2001.

The principal importance of rubella lies in its devastating effects on the fetus in utero, producing teratogenic effects and a continuing congenital infection (congenital rubella syndrome). The control of rubella is so successful that the number of cases worldwide of reported congenital rubella syndrome in 2008 was only 165 with over one-third of these from the Eastern Mediterranean region. In the United States, congenital rubella syndrome is eliminated since 2004. Two reported cases of congenital rubella syndrome between 2005 and 2007 were imported from Nigeria and Cote d’Ivoire.

Clinical Findings

A. Symptoms and Signs

While fetal rubella can be devastating, postnatally acquired rubella is usually innocuous with up to 50% cases asymptomatic. In the postnatally acquired infection, fever and malaise, usually mild, accompanied by tender suboccipital adenitis, may precede the eruption by 1 week. Mild coryza may be present. Polymarticular arthritis occurs in about 25% of adult cases and involves the fingers, wrists, and knees. Rarely does chronic arthritis develop. The polyarthritis usually subsides within 7 days but may persist for weeks. Early posterior cervical and postauricular lymphadenopathy is very common. Erythema of the palate and throat, sometimes patchy, may be noted.

A fine, pink maculopapular rash appears on the face, trunk, and extremities in rapid progression (2–3 days) and fades quickly, usually lasting 1 day in each area (Table 32–2). Rubella without rash may be at least as common as the exanthematous disease. Diagnosis, when suspected because of disease in the community, requires serologic confirmation.

B. Laboratory Findings

Leukopenia may be present early and may be followed by an increase in plasma cells. The definitive diagnosis of acute rubella infection is based on elevated IgM antibody, fourfold or greater rise in IgG antibody titers, or isolation of the virus. False-positive IgM antibodies, however, are associated with Epstein-Barr virus, cytomegalovirus, erythrovirus (parvovirus), and rheumatoid factor. Detection of antibodies against rubella in other body fluids, such as urine and saliva, are promising diagnostic aids. An interferon-gamma-ELISPOT can provide valuable additional information in seronegative individuals. PCR techniques are also available.
Complications

A. Exposure During Pregnancy

When a pregnant woman is exposed to a possible case of rubella, an immediate hemagglutination-inhibiting rubella antibody level should be obtained to document immunity, since fetal infection during the first trimester leads to congenital rubella in at least 80% of fetuses.

Positive tests for IgG antibodies alone indicate past infection or vaccination. High-avidity anti-rubella IgG assays may distinguish past infection from vaccination. If no antibodies are found, clinical observation and serologic follow-up are essential. An isolated IgM-positive test needs to be interpreted with caution because it does not necessarily imply acute infection. Confirmation of rubella in the expectant mother raises the question of therapeutic abortion, an alternative to be considered in light of personal, religious, legal, and other factors.

The immune status of the mother needs to be evaluated because titers fall to seronegativity in about 10% by 12 years after vaccination.

B. Congenital Rubella

An infant acquiring the infection in utero may be normal at birth but probably—50% in a series of nearly 70 pregnant women with rubella in Mexico—will have a wide variety of manifestations, including early-onset cataracts and glaucoma, microphthalmia, hearing deficits, psychomotor retardation, congenital heart defects (patent ductus arteriosus, branch pulmonary artery stenosis), organomegaly, and maculopapular rash. In general, the younger the fetus when infected, the more severe the illness. Deafness is the primary complication in the second trimester. Viral excretion in the throat and urine persists for many months despite high antibody levels. A specific test for IgM rubella antibody is useful for diagnosis in the newborn. A confirmatory diagnosis is made by isolation of the virus or PCR detection of viral RNA in tissues. Treatment is directed toward the many anomalies.

C. Postinfectious Encephalopathy

In 1:6000 cases, postinfectious encephalopathy develops 1–6 days after the rash; the virus cannot always be isolated. The mortality rate is 20%, but residual deficits are rare among the recovered. The mechanism is unknown.

Other unusual complications of rubella include hemorrhagic manifestations due to thrombocytopenia and vascular damage, duodenal stenosis, and mild hepatitis.

Treatment

Acetaminophen provides symptomatic relief for acute rubella. Encephalitis and non–life-threatening thrombocytopenia should be treated symptomatically.

Prognosis

Rubella is a mild illness and rarely lasts more than 3–4 days. Congenital rubella, on the other hand, has a high mortality rate, and the associated congenital defects are largely permanent.

Prevention

Live attenuated rubella virus vaccine should be given to all infants and a second dose should be given to children of school age. It is important that girls in particular are immune to rubella prior to the menarche. When women are immunized, they should not be pregnant, and the absence of antibodies should be established. (In the United States, about 80% of 20-year-old women are immune to rubella.) Postpartum administration to susceptible female hospital employees is recommended. It is recommended that women not become pregnant for at least 3 months after vaccine administration. Nonetheless, there are no reports of congenital rubella syndrome after rubella immunization, and inadvertent immunization of a pregnant woman is not considered an indication for therapeutic abortion. Arthritis is more marked after rubella vaccination than in native disease and appears to be immunologically mediated. A flare of juvenile rheumatoid arthritis after rubella vaccination is reported. The association between chronic arthropathies and rubella vaccination is controversial. Anaphylactoid reactions following vaccination are rare, and a self-limited thrombotic thrombocytopenic purpura is a reported but very rare (2.6 per 100,000 doses) complication. The immune response to rubella vaccination is mediated by several polymorphisms in vitamin A receptor and innate immunity genes. MMR may be given in conjunction with DPT or varicella boosters as adequate serologic responses are documented. The administration of two or more doses appears to overcome an immunogenetic risk for vaccine failure in some vaccinees. Immunogenicity is similar with intramuscular and intracutaneous infection, for MMR and varicella vaccinations. Children with biliary atresia in particular show impaired responses to MMR and varicella vaccinations. Preliminary data suggests that the vaccination of transplant (solid organ, bone marrow, and stem cell) patients on immunosuppressive therapy may be safe.

When to Refer

- Pregnancy.
- Meningitis/encephalitis.
- Significant vaccination reactions.
- Any suspect cases should be reported to public health authorities.

1. Rabies

### ESSENTIALS OF DIAGNOSIS

- History of animal bite.
- Paresthesia, hydrophobia, rage alternating with calm.
- Convulsions, paralysis, thick tenacious saliva.

#### General Considerations

Rabies is a viral (rhabdovirus) encephalitis transmitted by infected saliva that gains entry into the body by an animal bite or an open wound. Worldwide, 17.4 million cases of animal bites are reported every year, and more than 50,000 deaths are attributed to rabies. Most of these cases occur in rural areas of Africa and Asia, with India accounting for 36% of the global deaths. In developing countries, more than 90% of human cases are secondary to bites from infected dogs. Rabies among travelers to rabies-endemic areas is usually associated with animal injuries (including dogs in North Africa and India, cats in the Middle East, and non-human primates in sub-Saharan Africa and Asia), with most travel-associated cases occurring within 10 days of arrival. In the United States, domestically acquired rabies cases are rare (approximately 92% of cases are associated with wildlife) but probably underreported. In 2010, 6154 cases of animal rabies and 2 cases of bat-associated human rabies were reported in the United States. Wildlife reservoirs, each species having its own rabies variant(s), follow a unique geographic distribution in the United States: raccoons in the East Coast; skunks in the Midwest, Southwest, and California; and foxes in the Southwest and in Alaska. Hawaii is the only rabies-free state to date. Bats were the third most reported rabid animal after raccoons and skunks during 2010. Coyotes are also rabies-free. Rodents and lagomorphs (eg, rabbits) are unlikely to spread rabies because they cannot survive the disease long enough to transmit it (woodchucks and groundhogs are exceptions). Wildlife epizootics present a constant public health threat in addition to the danger of reintroducing raccoons to domestic animals. Vaccination is the key to rabies in small animals and rabies transmission to human beings.

The virus gains entry into the salivary glands of dogs 5–7 days before their death from rabies, thus limiting their period of infectivity. Less common routes of transmission include contamination of mucous membranes with saliva or brain tissue, aerosol transmission, and corneal transplantation. Transmission through solid organ and vascular segment transplantation from donors with unrecognized infection is also reported.

The incubation period may range from 10 days to many years but is usually 3–7 weeks depending in part on the distance of the wound from the CNS. The virus travels in the nerves to the brain, multiplies there, and then migrates along the efferent nerves to the salivary glands. Rabies virus infection forms cytoplasmic inclusion bodies similar to Negri bodies. These Negri body-like structures are thought to be the sites of viral transcription and replication.

#### Clinical Findings

##### A. Symptoms and Signs

While there is usually a history of animal bite, bat bites may not be recognized. The prodromal syndrome consists of pain at the site of the bite in association with fever, malaise, headache, nausea, and vomiting. The skin is sensitive to changes of temperature, especially air currents (aerophobia). Percussion myoedema can be present and persist throughout the disease. The CNS stage begins about 10 days after the prodome and may be either encephalitic (“furious”) or paralytic (“dumb”). The encephalitic form (about 80% of the cases) produces the classic rabies manifestations of delirium alternating with periods of calm, extremely painful laryngeal spasms on attempting drinking (hydrophobia), autonomic stimulation (hypersalivation), and seizures. In the less common paralytic form, an acute ascending paralysis resembling Guillain-Barré syndrome predominates with relative sparing of higher cortical functions initially. Both forms progress relentlessly to coma, autonomic nervous system dysfunction, and death.

##### B. Laboratory Findings

Biting animals that appear well should be quarantined and observed for 10 days. Sick or dead animals should be tested for rabies. A wild animal, if captured, should be sacrificed and the head shipped on ice to the nearest laboratory qualified to examine the brain for evidence of rabies virus. When the animal cannot be examined, raccoons, skunks, bats, and foxes should be presumed to be rabid.

Direct fluorescent antibody testing of skin biopsy material from the posterior neck (where hair follicles are highly innervated) has a sensitivity of 60–80%.

Quantitative reverse transcriptase-PCR, nucleic acid sequence-based amplification, direct rapid immunohistochemical test and viral isolation from the cerebrospinal fluid or saliva are advocated as definitive diagnostic assays. Antibodies can be detected in the serum and the cerebrospinal fluid. Pathologic specimens often demonstrate round or oval eosinophilic inclusion bodies (Negri bodies) in the cytoplasm of neuronal cells, but the finding is neither sensitive nor specific. MRI signs are diffuse and nonspecific.

#### Treatment & Prognosis

Management requires intensive care with attention to the airway, maintenance of oxygenation, and control of seizures. Universal precautions are essential. The induction of coma by ketamine, midazolam, and supplemental barbiturates along with the use of amantadine and ribavirin (the Milwaukee protocol) was reportedly helpful in one case but has failed to reproduce success in subsequent cases. Corticosteroids are of no use.

If postexposure prophylaxis (discussed below) is given expeditiously, before clinical signs develop, it is nearly
100% successful in prevention of disease. Once the symptoms have appeared, death almost inevitably occurs after 7 days, usually from respiratory failure. Most deaths occur in persons with unrecognized disease who do not seek medical care or in individuals who do not receive postexposure prophylaxis. Up to date, there are only seven cases of rabies that survived to hospital discharge after clinical symptoms started, only one of them did not receive the postexposure prophylaxis (index Milwaukee protocol case) and survived with naturally acquired immunity. Since 2004, the Milwaukee protocol has been applied to 26 additional patients with only one surviving to hospital discharge. The very rare cases in which patients recover without intensive care are referred to as “abortive rabies.”

Prevention

Immunization of household dogs and cats and active immunization of persons with significant animal exposure (eg, veterinarians) are important. The most important decisions, however, concern animal bites. Animals that are frequent sources of infection to travelers are dogs, cats, and non-human primates.

In the developing world, education, surveillance, and animal (particularly dog) vaccination programs are preferred over mass destruction of dogs, which is followed typically by invasion of susceptible feral animals into urban areas. In some Western European countries, campaigns of oral vaccination of wild animals led to the elimination of rabies in wildlife.

A. Local Treatment of Animal Bites and Scratches

Thorough cleansing, debridement, and repeated flushing of wounds with soap and water are important. Rabies immune globulin or antiserum should be given as stated below. Wounds caused by animal bites should not be sutured.

B. Postexposure Immunization

The decision to treat should be based on the circumstances of the bite, including the extent and location of the wound, the biting animal, the history of prior vaccination, and the local epidemiology of rabies. Any contact or suspect contact with a bat is usually deemed a sufficient indication to warrant prophylaxis. Consultation with state and local health departments is recommended. Postexposure treatment including both immune globulin and vaccination should be administered as promptly as possible when indicated.

The optimal form of passive immunization is human rabies immune globulin (HRIG; 20 international units/kg), administered once. As much as possible of the full dose should be infiltrated around the wound, with any remaining injected intramuscularly at a site distant from the wound. Finger spaces can be safely injected without development of a compartment syndrome. If HRIG is not available, equine rabies antiserum (40 international units/kg) can be used if available after appropriate tests for horse serum sensitivity. All of the rabies immunoglobulin should be injected at the wound site as much as possible and the remainder injected intramuscularly at a distant site from the vaccine administration.

Two vaccines are licensed and available for use in humans in the United States: a human diploid cell vaccine and a purified chick embryo cell vaccine. The current vaccines may be given as four injections of 1 mL intramuscularly in the deltoid or, in small children, into the anterolateral thigh muscles on days 0, 3, 7, and 14 after exposure. (The fifth dose at 28 days after exposure is no longer recommended except among immunosuppressed patients.) The vaccine should not be given in the gluteal area due to suboptimal response. An alternative vaccination strategy that only takes 1 week, with injections on days 0, 3, and 7 after exposure with a vero cell vaccine is under study in Thailand.

Rabies vaccines and HRIG should never be given in the same syringe or at the same site. Allergic reactions to the vaccine are rare, although local reactions (pruritus, erythema, tenderness) occur in about 25% and mild systemic reactions (headaches, myalgias, nausea) in about 20% of recipients. Adverse reactions to HRIG seem to be more frequent in women and rare in young children. The vaccine is commercially available or can be obtained through health departments.

Globally diverse anti-rabies vaccines are used. After Pasteur’s research in the 19th century with increasingly virulent strains, the first licensed vaccine (1911) was inactivated and grown on bovine brain tissue. Subsequent vaccines were grown using duck or chick embryo cells but remained allergenic. Increasingly purified vaccines are now grown on verocells, and a sixth-generation vero cell rabies vaccine is under development. In some countries, the full spectrum of vaccines, from human diploid rabies to chromatographically purified rabies vaccine are available, whereas in others, the gamut is smaller and intradermal application of smaller vaccine doses at multiple sites and at different times is commonly practiced in an attempt to lower costs, and is deemed safe and effective by the World Health Organization.

In patients with history of past vaccination, the need for HRIG is eliminated (RIG is in short supply worldwide) but postexposure vaccination is still required. The vaccine should be given 1 mL in the deltoid twice (on days 0 and 3). Neither the passive nor the active form of post-exposure prophylaxis is associated with fetal abnormalities and thus pregnancy is not considered a contraindication to vaccination.

C. Preexposure Immunization

Preexposure prophylaxis with three injections of human diploid cell vaccine intramuscularly (1 mL on days 0, 7, and 21 or 28) is recommended for persons at high risk for exposure: veterinarians (who should have rabies antibody titers checked every 2 years and be boosted with 1 mL intramuscularly); animal handlers; laboratory workers; Peace Corps workers; and travelers with stays over 1 month to remote areas in endemic countries in Africa, Asia, and Latin America. An intradermal route is also available (0.1 mL on days 0, 7, and 21 over the deltoid) but not in the
United States. Immunosuppressive illnesses and agents including corticosteroids as well as antimalarials—in particular chloroquine—may diminish the antibody response. A single dose booster at 10 years after initial immunization increases the level of antibody titers.

► When to Refer

Suspicion of rabies requires contact with public health personnel to initiate appropriate passive and active prophylaxis and observation of suspect cases.

► When to Admit

- Respiratory, neuromuscular, or CNS dysfunction consistent with rabies.
- Patients with suspect rabies require initiation of therapy until the disease is ruled out in suspect animals, and this requires coordination of care based on likelihood of patient compliance, availability of inpatient and outpatient facilities, and response of local public health teams.

2. Arbovirus Encephalitides

**ESSENTIALS OF DIAGNOSIS**

- Fever, malaise, stiff neck, sore throat, and vomiting, progressing to stupor, coma, and convulsions.
- Upper motor neuron lesion signs: exaggerated deep tendon reflexes, absent superficial reflexes, and spastic paralys.
- Cerebrospinal fluid opening pressure and protein are often increased, with lymphocytic pleocytosis.

► General Considerations

The arboviruses are arthropod-borne pathogens that produce clinical manifestations in humans. The mosquito-borne pathogens that cause encephalitis include three togaviruses (causing Western, Eastern, and Venezuelan equine encephalitis), five flaviviruses (causing West Nile fever, St. Louis encephalitis, Japanese B encephalitis, dengue, and Murray Valley encephalitis), and bunyaviruses (the California serogroup of viruses, including the Larcrosse agent of California encephalitis). The tick-borne causes of encephalitis include the flavivirus of the Powassann encephalitis (northeastern United States and Canada) and tick-borne encephalitis virus of Europe; and the Colorado tick fever reovirus. Tick-borne encephalitis virus, Colorado tick fever, and the arboviruses associated with viral hemorrhagic fever (including dengue) are discussed below, and only those viruses causing primarily encephalitis in the United States will be discussed here, although West Nile agent is being reported in many other areas, especially western Europe with recent cases from Greece, Portugal, and Hungary.

The reported total number of cases in the United States for all but the West Nile virus is low. The 2010 tally of reported patients includes 68 with the La Crosse agent of California encephalitis (22 alone in North Carolina), 10 with Eastern equine encephalitis (4 in Florida), and 8 each with Powassan encephalitis and St Louis encephalitis (5 in Texas and Arkansas). There are no reported patients with Western equine encephalitis since 1999.

Infection with West Nile virus was first identified in the United States in the New York City area in 1999. The virus spread rapidly, and current cases are reported throughout the continental United States. The homeless appear to be at particularly increased risk for infection. In the United States during 2011, 690 cases of West Nile virus disease were reported from all 50 states and the District of Columbia. Among these, there were 216 (31.3%) cases of neuroinvasive disease (0.07 per 100,000), with an increased incidence in the elderly. There were 43 deaths. Among blood donors testing seropositive, an additional 130 presumptively infected patients were identified.

Pathogen-specific reservoirs (typically small mammals or birds) are responsible for maintaining the encephalitis-producing viruses in nature. For the Eastern equine encephalitis virus, cotton rats and house sparrows were recently shown to serve as amplifying reservoirs. Birds are the main reservoir for West Nile virus and substantial avian mortality accompanies West Nile fever outbreaks (chicken surveillance is a recommended and possible mode of disease surveillance). The mosquito species associated with transmission is different in the Western vs Eastern United States (Culex tarsalis vs Culex pipiens) and consequently the terrain associated with high prevalence areas differs (open grasslands vs urban areas).

Outbreaks tend to occur in late summer and early fall and climatic factors, including elevated mean temperatures and rainfall, are shown to correlate with increased West Nile infection. Only dengue and Venezuelan equine encephalitis viruses produce viremias high enough to allow continued transmission to other mosquitoes and ticks. Human to human transmission of the other arboviruses is usually related to blood (including granulocyte) transfusion or organ transplantation (although most infected donors give a history of clinically significant disease). West
Nile virus perinatal, transplacental, breastfeeding (rarely), laboratory, and possibly aerosol transmission can also occur. Rare case reports of West Nile virus infection follow solid organ transplant. It is estimated that fever develops in 1 of 5 patients infected with West Nile virus, while severe neurologic disease presents in 1 of 150. St. Louis encephalitis and Powassan encephalitis occur among adults; Western equine encephalitis, Venezuelan equine encephalitis, and California encephalitis occur primarily among children, while West Nile fever and Eastern equine encephalitis are diseases of both children and adults.

Clinical Findings

A. Symptoms and Signs

The human incubation period for arboviral encephalitides is 2–14 days. Symptoms include fever, malaise, sore throat, headache, gastrointestinal upset, lethargy, and stupor progressing to coma. Using blood donor surveys, it is estimated that only about 26% of infections are symptomatic (women and the highly viremic are more symptomatic). A nonpruritic maculopapular rash is variably present. Stiff neck and mental status changes are the most common neurologic signs. About 50% of hospitalized patients with West Nile virus infection in the United States have significant muscle weakness that may be initially confused with the Guillain-Barré syndrome. Acute flaccid (poliomyelitis-like) paralysis is seen in 10% of West Nile virus neuroinvasive disease and less commonly with the other arboviruses. Other signs include tremors, seizures, cranial nerve palsies, and pathologic reflexes. Myocarditis, pancreatitis, and hearing loss are also reported. The disease manifestations associated with West Nile virus infection are strongly age-dependent: the acute febrile syndrome and mild neurologic symptoms (but on occasion meningitis) are more common in the young, aseptic meningitis and poliomyelitis-like syndromes are seen in the middle aged, and frank encephalopathy is seen more often in the elderly. All forms of disease tend to be severe in immunocompromised persons in whom neuroinvasive manifestations and associated high mortality are more apt to develop.

B. Laboratory Findings

The peripheral white blood cell count is variable. Cerebrospinal fluid protein is elevated; cerebrospinal fluid glucose is normal; there is usually a lymphocytic pleocytosis; and polymorphonuclear cells may predominate early. The diagnosis of arboviral encephalitides depends on serologic tests. Antibodies to arboviruses persist for life and the presence of IgG in the absence of a rising titer of IgM may indicate past exposure rather than acute infection. Individuals with chronic symptoms after West Nile virus infection may show persistent renal infection for up to 6 years with West Nile virus RNA present in urine. Documentation of a fourfold increase in acute/convalescence titers IgG or the presence of IgM antibodies is confirmatory. For West Nile virus, an IgM capture ELISA in serum or cerebrospinal fluid is almost always positive by the time the disease is clinically evident, and the presence of IgM in cerebrospinal fluid indicates neuroinvasive disease. These tests are available commercially but also through local or state health departments. Cross-reactivity exists among the different flaviviruses, so a plaque reduction assay may be needed to definitively distinguish between West Nile fever and St. Louis encephalitis. PCR assays (also available through the CDC) are less sensitive than serologic tests for the diagnosis of acute infections but are the preferred method for screening blood products and may be particularly useful in immunocompromised patients with abnormal antibody responses. CT scans of the brain usually show no acute disease, but MRI may reveal leptomeningeal, basal ganglia, thalamic, or periventricular enhancement.

Differential Diagnosis

Mild forms of encephalitis must be differentiated from aseptic meningitis, lymphocytic choriomeningitis, and nonparalytic poliomyelitis. Severe forms of arbovirus encephalitides are to be differentiated from other causes of viral encephalitis (HSV, mumps virus, poliovirus or other enteroviruses, HIV), encephalitis accompanying exanthematous diseases of childhood (measles, varicella, infectious mononucleosis, rubella), encephalitis following vaccination (a demyelinating type following rabies, measles, pertussis), toxic encephalitis (from drugs, poisons, or bacterial toxins such as Shigella dysenteriae type 1), Reye syndrome, and severe forms of stroke, brain tumors, brain abscess, autoimmune processes such as lupus cerebritis, and intoxications. In the California Encephalitis Project, the cause for most cases of encephalitis was not identified.

Complications

Bronchial pneumonia, urinary retention and infection, prolonged weakness, and decubitus ulcers may occur. St. Louis encephalitis is reportedly associated with a postinfectious encephalomyelitis. A chronic syndrome consisting of myalgias, arthralgias, and difficulty with concentration and memory is reported in over half the symptomatic cases.

Treatment

Although specific antiviral therapy is not available for most causative entities, vigorous supportive measures can be helpful. Such measures include reduction of intracranial pressure (mannitol) and monitoring of intraventricular pressure. The efficacy of corticosteroids in these infections is not established. Preliminary evidence that ribavirin is useful in West Nile virus encephalitis is not substantiated. Other therapeutic options such as IVIG or interferon-α await confirmation of effectiveness. A recent case report suggests that prophylaxis with West Nile virus hyperimmune plasma and gamma globulin may prevent neuroinvasion.
Prognosis

Although most infections are mild or asymptomatic, the prognosis is always guarded, especially at the extremes of age. Homozygosity for a 32bp deletion in the gene coding for the chemokine receptor CCR5, associated with complete loss of function, predisposes to symptomatic West Nile virus infection. People with this mutation are resistant to acquiring HIV infection. Between January and October 2011, the case fatality rate for West Nile virus disease in the United States was 6.2% (43 of 690). Age older than 50 years is the most important risk factor for severe disease and death. Other risk factors for mortality include black race, chronic kidney disease, hepatitis C virus infection, and immunosuppression. Recovery of persons with severe neurologic compromise may take months. Sequelae of West Nile virus infection include a poliomyelitis-like syndrome, cognitive complaints, movement disorders, epilepsy, and depression; and they may become apparent late in the course of what appears to be a successful recovery.

The long-term prognosis is generally better for Western equine than for Eastern equine or St. Louis encephalitis.

Prevention

No human vaccine is currently available for the arboviruses prevalent in North America, although yellow fever virus-based chimeric vaccines and recombinant vaccines are under development for West Nile virus. Mosquito control (repellents, protective clothing, and insecticides) is effective in prevention. Since 2003, all blood donations in the United States are screened with nucleic acid amplification tests for West Nile virus. Laboratory precautions are indicated for handling all these pathogens, in particular the West Nile virus.

A vaccine against Japanese B encephalitis is recommended for travelers to rural areas of East Asia, though the risk of disease acquisition among the exposed is estimated at only 1:1,000,000. This vaccination appears to provide some protection against West Nile virus (both agents are related flaviviruses).

and maculopapular rash. After 3–5 days the fever subsides only to return after 2–4 days alongside the meningeal phase, characterized by headache, nausea and vomiting, lethargy, and variably present meningeal signs. Arthralgias can develop late in the course. Transverse myelitis, deafness, Guillain-Barré syndrome and transient and permanent hydrocephalus are reported. As stated above, lymphocytic choriomeningitis virus is a well known, albeit underrecognized, cause of congenital infection frequently complicated with obstructive hydrocephalus and chorioretinitis, leading to an infant mortality of up to 30%. Occasionally, a syndrome resembling the viral hemorrhagic fevers (see below) is described in transplant recipients of infected organs and in patients with lymphoma.

B. Laboratory Findings
Leukocytosis or leukopenia and thrombocytopenia may be initially present. During the meningeal phase, cerebrospinal fluid analysis frequently shows lymphocytic pleocytosis (total count is often 500–3000/mcL) alongside a slight increase in protein, while a low to normal glucose is seen in at least 25%. The virus may be recovered from the blood and cerebrospinal fluid by mouse inoculation. Complement-fixing antibodies appear during or after the second week. Detection of specific IgM by ELISA is becoming widely used. Detection of lymphocytic choriomeningitis virus by PCR is available in research settings.

Differential Diagnosis
The influenza-like prodrome and latent period may distinguish this from other aseptic meningitides, and bacterial and granulomatous meningitis. A history of exposure to mice or other potential vectors is an important diagnostic clue.

Treatment
Treatment is supportive. In the survivor of a transplant-associated outbreak, ribavirin (which is effective against other arenaviruses) was used successfully along with decreasing immunosuppression.

Prognosis
Fatals are rare. The illness usually lasts 1–2 weeks, though convalescence may be prolonged. Congenital infection is more severe with about 30% mortality rate among infected infants, and more than 90% of survivors suffering long-term neurologic abnormalities.

Prevention
Pregnant women should be advised of the dangers to their unborn children inherent in exposure to rodents.

4. Prion Diseases

ESSENTIALS OF DIAGNOSIS

- Rare in humans.
- Cognitive decline.
- Myoclonic fasciculations, ataxia, visual disturbances, pyramidal and extrapyramidal symptoms.
- Variant form presents in younger people with prominent psychiatric or sensory symptoms.
- Specific EEG patterns.

General Considerations
Transmissible spongiform encephalopathies is a group of fatal neurodegenerative diseases affecting humans and animals. They are caused by infectious proteins called prions for proteinaceous infectious particles. These agents show slow replicative capacity and long latent intervals in the host. They induce the conformational change of a normal brain protein (prion protein; PrP[C]) into an abnormal isof orm (PrP[Sc]) that accumulates and causes neuronal vacuolation (spongiosis), reactive proliferation of astrocytes and microglia and, in some cases, the deposition of beta-amyloid oligomeric plaques (PrP[Sc]).

Prion disease can be hereditary, sporadic, and transmissible in humans. Hereditary disorders are caused by germ line mutations in the PrP[C] gene causing familial Creutzfeldt-Jakob disease (fCJD), Gerstmann-Sträussler-Scheinker syndrome (GSS), and fatal familial insomnia. Variations at PrP codons sites, in particular codon 129 but also codons 114, 178, 180, and 232, determine host susceptibility to prion disease and the different phenotypes of the disease.

Sporadic Creutzfeldt-Jakob disease (sCJD) is the most common of the human prion diseases, accounting for approximately 85% of cases; it has no known cause, although a spontaneous misfolding of PrP[C] as well as somatic mutations of PrP[C] or undetectable horizontal transmission are postulated as possible explanations. Transmissible prion disease is only described for kuru and Creutzfeldt-Jakob disease in its iatrogenic (iCJD) and variant (vCJD) form. Iatrogenic transmission of CJD is associated with prion contaminated human corneas, dura mater grafts, growth hormone, gonadotropins, stereotactic electroencephalography, electrodes, and neurosurgical instruments. Kuru, once prevalent in central New Guinea, is now rare, a decline in prevalence that started after the abandonment of cannibalism in the late 1950s (a protective allele of the PrP gene is now identified at codon 127).

More than 200 cases of vCJD (bovine spongiform encephalopathy [BSE] or “mad cow disease”) were reported in the United Kingdom since the first documented cases there in the mid-1990s. It is far less common in North America, with only 3 cases reported in the United States (the last 1 in 2006) and 19 in Canada. Of the US reported cases, none acquired the disease locally (2 of them acquired...
the infection in the United Kingdom and 1 in Saudi Arabia). This disease is characterized by its bovine-to-
human transmission through ingestion of meat from cattle infected with BSE. There is no animal-to-animal spread of
BSE, and milk and its derived products are not considered to be infected. Reports of secondary transmission of vCJD
due to blood transfusions from asymptomatic donors are reported in the United Kingdom. Although iCJD and vCJD
are not associated with a known PrP gene mutation, a polymorphism in codon 129 is prevalent and seems to deter-
mine susceptibility and expression of clinical disease. The overall annual incidence of prion disease worldwide is
approximately one in 1 million people per year. In the United States, among 2441 cases reported through August
19, 2011 to the US National Prion Disease Pathology Surveillance Center, 2068 (85%) were sporadic, 356 (15%)
reported in the United Kingdom. Although iCJD and vCJD are not associated with a known PrP gene mutation, a poly-
morphism in codon 129 is prevalent and seems to determine susceptibility and expression of clinical disease. The
overall annual incidence of prion disease worldwide is approximately one in 1 million people per year. In the
United States, among 2441 cases reported through August 19, 2011 to the US National Prion Disease Pathology
Surveillance Center, 2068 (85%) were sporadic, 356 (15%) familial, 5 (0.2%) iatrogenic, and 3 (0.1) vCJD.

► Clinical Findings

A. Symptoms and Signs

Both sCJD and fCJD usually present in the sixth or seventh decade of life, whereas the iCJD form tends to occur in
a much younger population. Clinical features of these three forms of disease usually involve mental deterioration
(dementia, behavioral changes, loss of cortical function) progressive over several months, as well as myoclonus,
extrapyramidal (hypokinesia) and cerebellar manifestations (ataxia, dystasia). Finally, coma ensues, usually
associated with an akinetic state and less commonly decerebrate/postural posture. Like iCJD, vCJD usually
affects younger patients (averaging ~28 years), but the duration of disease is longer (about 1 year). The degree of
organ involvement is often extensive, and the clinical symptoms are unique, mainly characterized by prominent
psychiatric and sensory symptoms. Kuru presents with an early stage of tremors, ataxia, and postural instability fol-
lowed by a sedentary stage characterized by involuntary movements (myoclonus, fasciculations, and choreoatheto-
sis) and a final stage of dementia. GSS, a rare inherited autosomal dominant (rarely sporadic) disorder that occurs
in kindred is rapidly fatal. It typically causes a disruption of the circadian sleep-activity pattern leading to insomnia,
hallucinations, behavioral changes, motor disturbance and, rarely, dementia. Fatal familial insomnia is the only
prion disease associated with endocrine disorders and dysautonomia.

B. Laboratory Findings

CJD should be considered as a diagnosis in the proper clinical scenario, in the absence of alternative diagnoses
after routine investigations. Abnormalities in cerebrospinal fluid are subtle and rarely helpful. The detection of
14–3–3 protein in the cerebrospinal fluid is helpful for the diagnosis of sCJD but not in vCJD and fCJD. Its sensitiv-
ity and specificity are widely variable among different studies. Cerebrospinal fluid detection of other proteins
like tau, neuron-specific enolase, and S100 protein are reported in smaller studies but do not as yet show clinical
utility. More recently, a new blood-based assay and a PCR

in cerebrospinal fluid showed some promising results and are currently under evaluation for clinical use.

In CJD, EEG typically shows a pattern of paroxysms with high voltages and slow waves, while MRI is character-
istic for bilateral areas of increased signal intensity, predominant in the thalami and putamina. In contrast, vCJD
shows a diffusely abnormal but nondiagnostic EEG. MRI characteristicly reveals hyperintensity of the posterior
thalami ("pulvinar sign"). Positron emission tomography can help distinguish GSS disease. The differentiation and
definitive diagnosis of these neurodegenerative diseases are ultimately established by neuropathologic confirmation.

► Treatment & Prevention

There is no specific treatment for CJD. Once symptoms appear, the infection invariably leads to death. Flupirtine
(an analgesic drug) is sometimes useful in slowing the associated cognitive decline but does not affect survival.

iatrogenic CJD can be prevented by limiting patient exposure to potentially infectious sources as mentioned
above. Disinfection of equipment requires autoclaving at 15 psi for 1 hour, and disinfection of contaminated
surfaces requires 5% hypochlorite or 0.1 N sodium hydroxide solutions. Prevention of vCJD relies on surveillance of
potentially infected livestock. The American Red Cross does not accept blood donations from persons with a family
history of CJD or with a history of dural grafts or pituitary-derived growth hormone injections.

Feb 5;377(9764):487–93. [PMID: 21295339]

5. Progressive Multifocal Leukoencephalopathy (PML)

PML is a rare demyelinating CNS disorder caused by the reactivation of the JC virus (John Cunningham virus or
JCV). This polyomavirus usually causes its primary infection during childhood with >60% of adults typically
being seropositive. The virus remains latent in the kidneys, lymphoid tissues, epithelial cells, peripheral blood
lymphocytes, bone marrow, and possibly brain until the time reactivation occurs and symptoms become evident
(see below). This reactivation is usually seen in adults with impaired cell-mediated immunity, especially AIDS
patients (5–10% of whom develop PML), as well as those with idiopathic CD4 lymphopenia syndrome. It is also
reported among those with lymphoproliferative and myeloproliferative disorders; granulomatous, inflammatory, and rheumatic diseases (systemic lupus erythematosus and rheumatoid arthritis in particular); as well as in those who have undergone solid and hematopoietic cell transplantation; and occasionally in those who have other medical states, including cirrhosis and renal failure.

Monoclonal antibody-associated PML is described with the use of natalizumab, rituximab, infliximab, and efalizumab (withdrawn from the market in April 2009). Natalizumab, a monoclonal antibody used in the treatment of multiple sclerosis, is associated with the risk of PML developing in 1.35 cases per 1000 patients treated for more than a year and 1.78 per 1000 for patients treatment > 2 years. Although an immune reconstitution inflammatory state may follow cessation of monoclonal antibody therapy, the JCV presence and the residual neurologic deficits may not clear for years after therapy is stopped. The risk of developing PML associated with rituximab is at least 1 in 25,000 exposed patients with cases reported in various autoimmune conditions (systemic lupus erythematosus, rheumatoid arthritis, multiple sclerosis). The mean interval between the use of the drug to the diagnosis of PML is 5.5 months. Only one case of infliximab-associated PML is reported. Smoking is reportedly associated with an increased risk of PML.

Clinical Findings
A. Symptoms and Signs
JCV causes lytic infection of oligodendrocytes in the white matter and symptoms presenting subacutely reflect the diverse areas of CNS involvement. Symptoms include altered mental status, aphasia, ataxia, hemiparesis or hemiplegia and visual field disturbances. Seizures occur in about 18%. Involvement of cranial nerves and cervical spine is rare.

B. Laboratory Findings
PCR for JCV in cerebrospinal fluid is used for diagnosis in patients with compatible clinical and radiologic findings. A quantitative PCR is more sensitive. Persistent JCV viremia and increasing urinary JCV DNA may be predictive of PML.

MRIs of the brain show multifocal areas of white matter demyelination without mass effect or contrast enhancement.

Treatment & Prevention
Limiting the immunosuppression state represents the mainstay of therapy for PML. Treatment of HIV with HAART reduces the incidence of PML, improves the clinical symptoms and reverses some of the radiographic abnormalities as well as improves the 1-year mortality rate, regardless of baseline CD4 count. Immune restoration, however, can induce worsening of the clinical picture in a small number of cases. Immune reconstitution syndromes do not alter mortality but are associated with a form of PML called non-determined leukoencephalopathy associated with a distinct chemokine polymorphism. Significant neurologic sequelae to PML infections are the rule and the deficits associated with monoclonal associated PML may persist for years.

Decreasing immunosuppression in non-AIDS patients with PML (eg, transplant patients) is also typically beneficial. Cidofovir may be beneficial in non-AIDS related cases while corticosteroids may be useful with immune reconstitution. Because the JCV infects cells through serotonin receptors, the use of risperidone and mirtazapine are recommended by some clinicians but the success of these agents remains anecdotal. Future reports will assess the role of small inhibitory RNAs. Plasma exchange, which theoretically reduces the plasma level of agents associated with PML, is used by some for the management of natalizumab-associated PML.

6. Human T Cell Lymphotropic Virus (HTLV)
HTLV-1 and -2 are retroviruses that infect CD4 and CD8 T cells respectively, where they persist as a lifelong latent infection. HTLV-1 currently infects approximately 20 million individuals worldwide. It is endemic to many regions in the world including southern Japan, the Caribbean, central and south Africa, South America, Eastern Europe, and Oceania. The Caribbean basin and Southwestern Japan show the highest prevalence of infection (4–37%). Conversely, HTLV-2 is mainly found in native populations of South (1–58%), Central (8–10%) and North America (2–13%) as well as African pygmy tribes.

In the United States, studies done in blood donors show a seroprevalence of HTLV-1 of 0.01% and HTLV-2 of 0.02%. The virus is transmitted horizontally (sex), vertically (intrauterine, peripartum, and breastfeeding), and parenterally (injection drug use and blood transfusion). Hence, a higher prevalence is seen among injection drug users.

Clinical Findings
A. Symptoms and Signs
HTLV-1 infection is associated with HTLV-1 adult T cell lymphoma/leukemia (ATL) and HTLV-1 associated myelopathy/tropical spastic paraparesis (HAM/TSP). In contrast, HTLV-2 is significantly less pathogenic, with few reported cases of HAM/TSP as well as other neurologic
manifestations. The causative association of HTLV-1 with ATL, attributed to the virally encoded oncoprotein tax, is well established. The lifetime risk of developing ATL among seropositive persons is estimated to be 3% in women and 7% in men, with an incubation period of at least 15 years. The mean age of diagnosis of ATL is 40–50 years in Central and South America and 60 years in Japan.

ATL clinical syndromes may be classified as chronic, acute (leukemic), smoldering, or lymphomatous. A primary cutaneous tumor is also described and shows a worse prognosis compared with the smoldering type. Clinical features of ATL include diffuse lymphadenopathy, maculopapular skin lesions that may evolve into erythroderma, organomegaly, lytic bone lesions, and hypercalcemia. Opportunistic infections, such as *Pneumocystis jiroveci* pneumonia and cryptococcal meningitis, are common.

HAM/TSP, associated with both HTLV-1 and HTLV-2, develops in 0.3–4% of seropositive individuals and is more common in women. A chronic inflammation of the spinal cord leads to progressive motor weakness and symmetric spastic paraparesis, nociceptive low back pain, and paraplegia with hyperreflexia. Bladder and sexual disorders (eg, dyspareunia), sensory disturbances, erectile dysfunction, and constipation are also common. A progressive cognitive impairment is seen with HAM/TSP in children. Both viruses can also induce motor abnormalities, such as leg weakness, impaired tandem walk, and vibration sense, without overt HTLV-associated myelopathy.

An HTLV-1 provirus load in peripheral blood mononuclear cells and cerebrospinal fluid cells, and an HTLV-1 mRNA load are proposed as markers of HAM risk and progression. HTLV positivity is associated with erythrocytosis, lymphocytosis (HTLV-2) and with thrombocytosis (HTLV-1).

HTLV-1 seropositivity is associated with an increased risk of tuberculosis and *Strongyloides stercoralis* hyperinfection. Crusted scabies and infective dermatitis are also associated. Inflammatory states associated with HTLV-1 infection include arthropathy, polymyositis, uveitis, Sjögren syndrome, vasculitis, cryoglobulinemia, infiltrative pneumonitis, and ichthyosis. An increased risk for bronchiololaveolar carcinoma in the presence of HTLV-1 is recently reported.

HTLV-2 is no longer considered to be associated with hairy cell leukemia. HTLV-2 appears to cause a myelopathy that is milder and slower to progress than HAM. All-cause and cancer mortality is higher among HTLV-2 seropositive patients.

HTLV-1/HIV coinfected is associated both with higher CD4 counts and a higher risk of HAM.

**B. Laboratory Findings**

The peripheral smear may show atypical lymphoid cells with basophilic cytoplasm and convoluted nuclei (flower cells) but the diagnostic standard is evidence of clonal integration of the proviral DNA genome into tumor cell. The identification of HTLV-1 antibodies supports the diagnosis.

**Treatment & Prevention**

Management of ATL consists mainly of chemotherapy, with allogeneic stem cell transplantation and the use of monoclonal antibodies (anti-CCR4 and anti-CD25). A new chemotherapy regimen in Japan using eight different agents shows a higher response rate than traditional biweekly CHOP (40% vs 25%). Therapy using interferon-α combined with zidovudine is effective in the smoldering type.

HAM is treated with a variety of immune-modulating agents (including corticosteroids) without consistent results. Combination of antiretrovirals does not show benefit. Interferon-α may be of some efficacy. Small controlled studies showed that plasmapheresis appears to result in some improvement in gait and sensory disturbance among PML patients.

Screening of the blood supply for HTLV-1 is required in the United States. There is significant cross-reactivity between HTLV-1 and HTLV-2 by serologic studies, but PCR can distinguish the two. Better assays to screen organ donors for HTLV-1 and -2 infections are needed.

**OTHER SYSTEMIC VIRAL DISEASES**

**1. Hemorrhagic Fevers**

This diverse group of illnesses results from infection with one of several single-stranded RNA viruses (members of the families Arenaviridae, Bunyaviridae, Filoviridae, and Flaviviridae). Filaviruses, such as the pathogens causing dengue and yellow fever (both with occasional hemorrhagic complications), are discussed in separate sections.

Lassa fever (an Old World arenavirus) is rodent associated and transmission usually occurs through aerosolized particles (from rodents or infected individuals). Transmission through direct contact with infected biologic fluids or tissues is also documented and food-borne transmission, while considered, is not definitively proven. Similar modes of transmission are assumed for Junin virus and other members of the New World Arenaviridae (Machupo virus, Sabia virus, Guanarito virus, and Whitewater Arroyo virus). Bats (fruit bats for Ebola) are the suspected reservoir for Ebola and Marburg viruses (Filoviridae) but their vectors are unknown. A subtype of Ebola (Bundibugyo) is reported in Uganda (earlier Ebola outbreaks occurred in Democratic Republic of Congo, Sudan, and one case in Côte d’Ivoire). Cases of Marburg hemorrhagic fever are reported in travelers exploring caves and mines inhabited by bats in endemic areas of sub-Saharan Africa. The bunyaviruses include the Crimean-Congo hemorrhagic fever (transmitted by infected animal
exposure or tick bite), the Rift Valley fever (transmitted by exposure to infected animal products or bite of an infected mosquito or flea), and the hantaviruses (associated with rodent exposure and discussed separately below). The geographic distribution of Crimean-Congo hemorrhagic fever, like that of its tick vector, is widespread with cases reported in Asia, the Middle East, and Eastern Europe. In 2002, Turkey experienced the largest reported outbreak with over 2500 cases. Hospital-associated transmission of Crimean-Congo hemorrhagic fever is well documented in Iran. Rift Valley fever causes outbreaks in sub-Saharan and Northern Africa, including a recent 2007 outbreak with 155 deaths in Kenya following heavy rainfalls and associated with three different lineages of the virus. Rift Valley cases are also confirmed outside the African continent, in Saudi Arabia, and Yemen.

A new bunyavirus, a phlebovirus, associated with fever and thrombocytopenia, was identified in 2010 in Central and Northeastern China and is named for its geographic distribution of Crimean-Congo hemorrhagic fever virus. This virus is well documented in Iran. Rift Valley fever causes outbreaks in sub-Saharan and Northern Africa, including a recent 2007 outbreak with 155 deaths in Kenya following heavy rainfalls and associated with three different lineages of the virus. Rift Valley cases are also confirmed outside the African continent, in Saudi Arabia, and Yemen.

A new bunyavirus, a phlebovirus, associated with fever and thrombocytopenia, was identified in 2010 in Central and Northeastern China and is named for its symptoms: the 

| Syndrome | Severe fever with thrombocytopenia syndrome |

Its differential diagnosis includes anaplasmosis, hemorrhagic fever with renal syndrome, or leptospirosis. The current candidate vector is a tick of the Ixodidae family. A mortality of 12% was noted among the first 171 patients.

### Clinical Findings

#### A. Symptoms and Signs

The incubation period can be as short as 2 days for the Rift Valley fever or as long as 21 days for Lassa fever. The clinical symptoms in the early phase of a viral hemorrhagic fever are very similar, irrespective of the causative virus, and resemble a flu-like illness or gastroenteritis. Hepatitis is common.

The late phase is more specific and is characterized by organ failure, persistent leukopenia, altered mental status, and hemorrhage. Exanthems and mucosal lesions can occur. The range of pathology described with Crimean-Congo hemorrhagic fever continues to grow and include cardiac failure, bilateral alveolar hemorrhages, and retinal hemorrhages. Rift Valley fever is reportedly associated with encephalitis and also retinitis. Adrenal dysfunction is a common sequela of this class of infections and a cause for the development of the late-stage shock associated with these infections. The case-fatality rate ranges from 5% to 30% and may be as high as 90% in Ebola fever. The convalescence period can be long and complicated. There is no evidence of chronic infection among survivors. Risk factors for complications in patients with Crimean-Congo hemorrhagic fever include advanced age, thrombocytopenia, prolonged clotting factor parameters, and hepatitis; risk factors for mortality include altered senso

#### B. Laboratory Findings

Laboratory features usually include thrombocytopenia, leukopenia, (although with Lassa fever leukocytosis is noted), anemia, increased hematocrit, elevated liver function tests, and findings consistent with disseminated intravascular coagulation (although less prominently in Lassa fever). Urinalysis can reveal proteinuria and hematuria.

Special care should be taken for handling clinical specimens of suspected cases. Laboratory personnel should be warned about the diagnostic suspicion and the CDC must be contacted for guidance (Special Pathogens Branch, 404-639-1115). Diagnosis may be made by growing the virus from blood obtained early in the disease, antigen detection (by ELISA), nucleic acid amplification (PCR techniques), or by demonstration of a significant specific fourfold or greater rise in antibody titer. Detection of Ebola virus antigen in oral fluid samples by ELISA and RT-PCR may be possible; sample collection in this manner will be useful since certain ethnic customs prohibit blood collection. These tests are generally available only through the CDC.

### Differential Diagnosis

The differential diagnosis for hemorrhagic fever includes meningococcemia or other septicemias, Rocky Mountain spotted fever, dengue, typhoid fever, and malaria. The likelihood of acquiring hemorrhagic fevers among travelers is low.

### Treatment

Patients should be placed in private rooms with standard contact and droplet precautions. Barrier precautions to prevent contamination of skin or mucous membranes should also be adopted by the caring personnel. Airborne precautions should be considered in patients with significant pulmonary involvement or undergoing procedures that stimulate cough.

Certain arenaviruses (the Lassa pathogen, Junin virus in its viscerotropic phase, Machupo virus) and bunyaviruses (the Congo-Crimean hemorrhagic fever and Rift Valley fever pathogens) respond to oral ribavirin if it is started promptly: 30 mg/kg as loading dose, followed by 16 mg/kg every 6 hours for 4 days and then 8 mg/kg every 8 hours for 3 days. The efficacy for postexposure ribavirin in the management of Lassa fever, other arenaviruses, or hospital-associated Crimean-Congo hemorrhagic fever remains anecdotal. However, if ribavirin is used, it should be given in a high loading dose (35 mg/kg orally followed by 15 mg/kg three times daily for 10 days) and only for high-risk settings (eg, needle stick injury, mucous membrane contamination, emergency resuscitative contact, or prolonged intimate exposure during transport).

The filoviruses and the flaviviruses do not respond to ribavirin. Live attenuated vaccines are available for Junin hemorrhagic fever and the Rift Valley fever, and they are under study for the Crimean-Congo hemorrhagic fever, Ebola, and Marburg viruses. In addition, recombinant vaccines are under development for most of these pathogens (including the Lassa fever virus but not the Junin hemorrhagic fever virus). Therapeutic interventions that target the hematologic system are either ineffective or only marginally effective.
When to Admit

- Persons with symptoms compatible with those of any hemorrhagic fever and who have traveled from a possible endemic area should be isolated for diagnosis and symptomatic treatment.
- Isolation is particularly important because diseases due to some of these agents, such as Ebola virus, are highly transmissible and carry a mortality rate of 50–90%.

Clinical Findings

A. Symptoms and Signs

A history of travel to a dengue-endemic area within 14 days of symptom onset is helpful in establishing a diagnosis of dengue. Dengue infection may range from asymptomatic to severe hemorrhagic fever to fatal shock (dengue shock syndrome). Dengue fever is usually a nonspecific, self-limited biphasic febrile illness. More than half of infected children are asymptomatic. The illness is more severe and begins more suddenly in adults. After an incubation period of 4–5 days, there is a sudden onset of high fever, chills, and “break bone” aching of the head, back, and extremities accompanied by sore throat, prostration, and malaise. There may be conjunctival redness. Initially, the skin appears flushed or blotched, but 3–4 days after the lysis of the fever, a maculopapular rash, which.spares palms and soles, appears in over 50% of cases. As the rash fades, localized clusters of petechiae on the extensor surface of the limbs become apparent. Up to 25% may manifest signs of cardiac involvement. Hepatitis frequently complicates dengue fever with acute fulminant hepatitis in up to 5%.

Dengue hemorrhagic fever usually affects children living in endemic areas and is most likely to occur in secondary infections and in infections with serotype 2. A few days into the illness, signs of hemorrhage such as ecchymoses, gastrointestinal bleeding, and epistaxis appear. Symptoms found more often among the dengue hemorrhagic fever subset of patients include restlessness, epistaxis, and abdominal pain. Gastroenterologic complications, including hemorrhage, tenderness, and ascites, are more common with dengue hemorrhagic fever and often require intensive care observation.

2. Dengue

EXPERTS OF DIAGNOSIS

- Exposure 7–10 days before onset.
- Sudden onset of high fever, chills, severe myalgias and arthralgias, headache, sore throat, and depression.
- Biphasic fever curve: initial phase, 3–7 days; remission, few hours to 2 days; second phase, 1–2 days.
- Biphasic rash: evanescent, then maculopapular, scarlatiniform, morbilliform, or petechial changes from extremities to torso.
- Leukopenia and thrombocytopenia in the hemorrhagic form.

General Considerations

Dengue is due to a flavivirus transmitted by the bite of the Aedes mosquito. It may be caused by one of four serotypes widely distributed globally between the tropics of Capricorn and Cancer. An estimated 50–100 million cases of dengue fever and several hundred thousand cases of dengue hemorrhagic fever occur each year with numbers growing in both dengue fever and dengue hemorrhagic fever as a consequence of climatic factors, travel, and urbanization. It is thus the most common and important vector-borne disease of humans, with 2.5 billion living in dengue-infected regions and major intermittent outbreaks including over 7000 in 2010 in Nepal. The incubation period is 3–15 days (usually 7–10 days). When the virus is introduced into susceptible populations, usually by viremic travelers, epidemic attack rates range from 50% to 70%. Dengue is endemic in the lower Rio Grande Valley and adjacent border towns, with 40% of Brownsville, Texas residents showing serologic evidence of past infection and the virus being detected in mosquito larvae among 30% of households. The seroprevalence of Haitians by age 3 is over 53%.

Severe epidemics of dengue hemorrhagic fever (serotype 3) occurred over the past 20 years in East Africa, Sri Lanka, and Latin America. Dengue is the second most common cause of fever (after malaria) in travelers returning from developing countries. In one US series based on CDC reports, the highest proportion of laboratory-confirmed and probable cases were among travelers returning from the Dominican Republic (121 cases, 20% of total), Mexico (55 cases, 9% of total) and India (43 cases, 7% of total). In general, the more advanced forms of disease (hemorrhagic fever and shock) occur less often in the Americas than in Asia. Since the 1980s, locally acquired cases of dengue are reported from Texas-Mexico border, and Key West, Florida. Health care–associated transmission (needlestick, mucocutaneous exposure or transplant related) and vertical transmission occur rarely.

Persons with symptoms compatible with those of any hemorrhagic fever and who have traveled from a possible endemic area should be isolated for diagnosis and symptomatic treatment.

Isolation is particularly important because diseases due to some of these agents, such as Ebola virus, are highly transmissible and carry a mortality rate of 50–90%.

Clinical Findings

A. Symptoms and Signs

A history of travel to a dengue-endemic area within 14 days of symptom onset is helpful in establishing a diagnosis of dengue. Dengue infection may range from asymptomatic to severe hemorrhagic fever to fatal shock (dengue shock syndrome). Dengue fever is usually a nonspecific, self-limited biphasic febrile illness. More than half of infected children are asymptomatic. The illness is more severe and begins more suddenly in adults. After an incubation period of 4–5 days, there is a sudden onset of high fever, chills, and “break bone” aching of the head, back, and extremities accompanied by sore throat, prostration, and malaise. There may be conjunctival redness. Initially, the skin appears flushed or blotched, but 3–4 days after the lysis of the fever, a maculopapular rash, which.spares palms and soles, appears in over 50% of cases. As the rash fades, localized clusters of petechiae on the extensor surface of the limbs become apparent. Up to 25% may manifest signs of cardiac involvement. Hepatitis frequently complicates dengue fever with acute fulminant hepatitis in up to 5%. Dengue hemorrhagic fever usually affects children living in endemic areas and is most likely to occur in secondary infections and in infections with serotype 2. A few days into the illness, signs of hemorrhage such as ecchymoses, gastrointestinal bleeding, and epistaxis appear. Symptoms found more often among the dengue hemorrhagic fever subset of patients include restlessness, epistaxis, and abdominal pain. Gastroenterologic complications, including hemorrhage, tenderness, and ascites, are more common with dengue hemorrhagic fever and often require intensive care observation.

Persons with symptoms compatible with those of any hemorrhagic fever and who have traveled from a possible endemic area should be isolated for diagnosis and symptomatic treatment.

Isolation is particularly important because diseases due to some of these agents, such as Ebola virus, are highly transmissible and carry a mortality rate of 50–90%.

A subset of patients (more often girls than boys) often with secondary infection, may progress to dengue shock syndrome in which acute fever, hemorrhagic manifestations, and marked capillary leak are prominent; the latter manifests as pleural effusions and ascites, and there is a tendency for shock to develop. In infants, even primary infection can lead to dengue shock syndrome. While the infection is difficult to distinguish from malaria, yellow fever, or influenza, the rash makes dengue far more likely. Continuous abdominal pain with vomiting, bleeding, a decrease in the level of consciousness, rash, conjunctival congestion, and hypothermia should raise concern about dengue shock syndrome. Acute kidney injury in dengue largely occurs with dengue shock syndrome and shows a high mortality. While acute severe hepatitis can occur with dengue, concomitant other hepatotropic agents are usually responsible.

Distinguishing between dengue and other causes of febrile illness in endemic areas is difficult. Fevers due to dengue are more often associated with neutropenia and thrombocytopenia and with myalgias, arthralgias/arthritis, and lethargy among adults.

B. Laboratory Findings

Leukopenia is characteristic, and elevated transaminases are found frequently in dengue fever. Thrombocytopenia, increased fibrinolysis, and hemoconcentration occur more often in the hemorrhagic form of the disease. Liver biochemical test abnormalities are nearly universal. Thrombocytopenia, plasma leakage, and acute hepatitis are identified as predictors of severe manifestations of dengue and higher mortality. The nonspecific nature of the illness mandates laboratory verification for diagnosis, usually with IgM and IgG ELISAs after the febrile phase. Virus may be recovered from the blood during the acute phase. PCR or detection of the specific viral protein NS1 by ELISA may be diagnostic during the first few days of infection and may be appropriate for febrile travelers. Immunohistochemistry for antigen detection in tissue samples can also be used. Because the erythrocyte sedimentation rate is normal in most cases, elevation may help with the differential. Chest radiographs in dengue hemorrhagic fever show infiltrates and effusions, which follow the course of laboratory abnormalities.

Complications

Usual complications include pneumonia, bone marrow failure, hepatitis, iritis, retinal hemorrhages and maculopathy, orchitis, and oophoritis. Depression and chronic fatigue, occurring more often in older women, are also reported. Neurologic complications (such as encephalitis, Guillain-Barré syndrome, phrenic neuropathy, subdural hematoma, and transverse myelitis) are less common, although encephalitic complications are increasingly recognized. Aplastic anemia and hemophagocytosis syndrome are very rare complications. Dengue is rarely associated with stroke in patients with focal neurologic deficit and encephalopathy. Maternal infection poses a risk for premature birth and hemorrhage in both the mother and the infant if infection occurs near term.

Bacterial superinfection occurs more commonly with advanced age, higher fever, gastrointestinal bleeding, kidney disease, and altered consciousness.

Treatment

Treatment entails the appropriate use of volume support (with Ringer lactate in moderately severe shock and colloids in more severe cases), blood products, and pressor agents, and acetaminophen rather than nonsteroidal anti-inflammatory drugs for analgesia. Activities are gradually restored during prolonged convalescences. Endoscopic therapy is useful in evaluating and managing gastrointestinal hemorrhage, although injection therapy with sclerosing agents is not beneficial in most dengue hemorrhagic states. Platelet counts do not usefully predict clinically significant bleeding. Platelet transfusions, however, should be considered for severe thrombocytopenia (< 10,000/mcL) or when there is evidence of bleeding. Monitoring vital signs and blood volume may help in anticipating the complications of dengue hemorrhagic fever or shock syndrome.

The efficacy of corticosteroids in the management of dengue is not proven. There is anecdotal evidence for the efficacy of intravenous anti-D globulin in the management of dengue hemorrhagic fever.

Prognosis

Fatalities are rare but do occur (and more often among girls and the very young), especially during epidemic outbreaks, with occasional patients dying of fulminant hepatitis. Renal failure in dengue shock syndrome portends an especially poor prognosis. Convalescence for most patients is slow.

Prevention

Available prophylactic measures include control of mosquitoes by screening and insect repellents, particularly during early morning and late afternoon exposures. Testing of blood supplies is increasingly necessary especially in endemic areas as dengue spreads.

Two tetravalent live attenuated reverse DNA-based and genetically modified chimeric dengue virus vaccines (one of which uses a yellow fever viral backbone) remain under study and are undergoing clinical trials.
vaccination of populations in areas where dengue is endemic. J Infect Dis. 2011 Feb;203(3):327–34. [PMID: 21208923]

3. Hantaviruses

ESSENTIALS OF DIAGNOSIS

- Transmitted by rodents and cause two clinical syndromes.
- Hemorrhagic fever with renal syndrome (HFRS): mild to severe illness.
- Hantavirus pulmonary syndrome (HPS): 40% mortality rate.
- Ribavirin is used with some success in HFRS.

General Considerations

Hantaviruses are enveloped RNA bunyaviruses naturally hosted in rodents, moles, and shrews. Currently, over 21 hantavirus strains are known to cause human disease. These differ in rodent hosts, geographic distribution, and degree of pathogenicity. Two major clinical syndromes are described: hemorrhagic fever with renal syndrome (HFRS) and hantavirus pulmonary syndrome (HPS). Each year, over 150,000 cases of these two syndromes occur globally, with HPS being far less common. While they share many clinical features, evidence over the past decade suggest that a specific strain is no longer associated with a specific syndrome, but different degrees of overlap are seen between both syndromes. Usually seen in the southwestern United States, Sin Nombre virus (Muerto Canyon, Four Corners) is the most common hantavirus infection in the United States and is the main North American virus responsible for HPS. Although retrospective diagnostics show that the disease occurred decades earlier, it was not until 1993 when the first outbreak was recognized in the United States. Through 2011, 580 cases were reported in 34 states. Other strains native to North America known to cause HPS include Bayou, Black Creek Canal, New York, and Monongahela viruses. Outbreaks of HPS associated with other hantavirus types are also reported in Central and South America.

Hantaviruses are ubiquitous, with infections described in North and South America (New World hantaviruses) as well as Europe, Africa, and Asia (Old World hantaviruses). The Hantaan viruses cause severe hemorrhagic fever with renal syndrome and are found primarily in Korea, China, and eastern Russia. The Seoul viruses produce a less severe form of disease and are found primarily in Korea and China. Cases of domestically acquired Seoul hantavirus were recently described in the United States. The Puumala and Dobrava viruses are found in Scandinavia and Europe and are associated with a usually milder form of the syndrome, termed “nephropathia epidemica,” which presents with fever, headache, gastrointestinal symptoms, and impaired kidney function.

Aerosols of virus-contaminated rodent urine and feces are thought to be the main vehicle for transmission to humans. Human to human transmission is rare and confined to one hantavirus, the Andes virus. Occupation is the main risk factor for transmission of all hantavirus, with animal trappers, forestry workers, laboratory personnel, farmers, and military personnel considered to be at highest risk. Climate change appears to be impacting the incidence of hantavirus infection mainly through effects on reservoir ecology.

Clinical Findings

A. Symptoms and Signs

Vascular leakage is the hallmark of the disease for both syndromes, with lungs being the main target on HPS and the kidneys on HFRS.

HPS is a more severe disease than HFRS, with a mortality rate of about 40%. The clinical course of HPS is divided into a febrile prograde, a cardiopulmonary stage, oliguric and diuretic phase followed by convalescence. A 14- to 17-day incubation period is followed by a prodromal phase, typically lasting 3–6 days, that is associated with myalgia, malaise, a fever of abrupt onset, gastrointestinal disturbance, headache, and chills. An ensuing cardiopulmonary phase is characterized by the acute onset of pulmonary edema. In this stage, cough is generally present, gastrointestinal manifestations may dominate the clinical presentations, and in severe cases, significant myocardial depression occurs. Acute kidney injury and myositis may occur. Sequelae include neuropsychological impairments in some HPS survivors.

HFRS manifests as mild, moderate, or severe illness depending on the causative strain, with a mortality rate of up to 12%. A 2- to 3-week incubation period is followed by a protracted clinical course, typically consisting of five distinct phases: febrile period, hypotension, oliguria, diuresis, and convalescence phase. Various degrees of renal involvement are usually seen, occasionally with frank hemorrhage. Pulmonary edema is not typically seen but when present usually occurs in the final stages of disease (oliguric and diuretic phase). Encephalitis and pituitary involvement are rare findings with hantavirus infection, although a few cases are reported with Puumala virus.

B. Laboratory Findings

Laboratory features include hemoconcentration and elevation in lactate dehydrogenase, serum lactate, and hepatocellular enzymes. Early thrombocytopenia and leukocytosis (as high as 90,000 cells/mL in HPS) are seen in both HFRS and HPS. In HPS, immunoblasts (activated lymphocytes with plasmacytoid features) can be seen in blood, lungs, kidneys, bone marrow, liver, and spleen. The severity of
4. Yellow Fever

ESSENTIALS OF DIAGNOSIS

- Endemic area exposure (tropical South and Central America, Africa, but not Asia).
- Sudden onset of severe headache, aching in legs, and tachycardia.
- Brief (1 day) remission, followed by bradycardia, hypotension, jaundice, hemorrhagic tendency.
- Proteinuria, leukopenia, bilirubinemia, bilirubinuria.
- Rare and potentially fatal reactions to vaccination.

**General Considerations**

Yellow fever is a zoonotic flavivirus infection transmitted by *Aedes* and jungle mosquitoes. It occurs in an urban and jungle cycle in Africa and in a jungle cycle in South America (where genetic studies suggest it arose through the slave trade 300–400 years ago). Epidemics have extended far into the temperate zone during warm seasons.

Infection is transmitted by an infected mosquito bite. The incubation period in humans is 3–6 days. Adults and children are equally susceptible, though attack rates are highest among adult males because of their work habits. Between 5% and 50% of infections are asymptomatic.

**Clinical Findings**

A. **Symptoms and Signs**

1. **Mild form**—Symptoms are malaise, headache, fever, retroorbital pain, nausea, vomiting, and photophobia. Relative bradycardia, conjunctival injection, and facial flushing may be present.

2. **Severe form**—Severe illness develops in about 15%. Initial symptoms are similar to the mild form, but a brief fever remission lasting hours to a few days is followed by a “period of intoxication” manifested by fever and relative bradycardia (Faget sign), hypotension, jaundice, hemorrhage (gastrointestinal, nasal, oral), and delirium that may progress to coma.

B. **Laboratory Findings**

Leukopenia occurs, although it may not be present at the onset. Kidney disease with proteinuria is present, sometimes as high as 5–6 g/L, and usually disappears completely with recovery. Levels of liver enzymes and bilirubin can be remarkably abnormal with the levels of aspartate aminotransferase (AST) usually doubling those of alanine aminotransferase (ALT). Prothrombin time may be elevated as well. Serologic diagnosis is made by using capture ELISA to measure IgM during the acute and convalescent phases. Viral culture is used in epidemic settings. Rapid test involving PCR and monoclonal antibodies assays against circulating viral antigens are becoming available.

**Prevention**

Because infection is thought to occur by inhalation of rodent wastes, prevention is aimed at eradication of rodents in houses and avoidance of exposure to rodent excreta in rural settings, including forest service facilities. Vaccine development is underway.

---

“nephropathia epidemica” correlates with plasma interleukin-6 levels.

The viremia of human hantavirus infections is short-term, and therefore, viral RNA cannot be readily detected in the blood or urine of patients. An indirect fluorescent assay and enzyme immunoassay are available for detection of specific IgM or low-avidity IgG virus-specific antibodies. A plaque reduction neutralization test is considered the gold standard serologic assay and distinguishes between the different hantavirus species, although cross reaction between Old World and New World viruses exist. This test needs to be performed in a laboratory with appropriate biosafety (level 3).

**Differential Diagnosis**

The differential diagnosis of the acute febrile syndrome seen with HFRS or early HPS includes scrub typhus, leptospirosis, and dengue. HPS requires differentiation from other respiratory infections caused by such pathogens as *Legionella*, *Chlamydia*, and *Mycoplasma*. Coxsackievirus infections should also be considered in the differential diagnosis.

**Treatment**

Treatment is mainly supportive. Cardiorespiratory support with vasopressors and sometimes extracorporeal membrane oxygenation are frequently needed in severe cases. Intravenous ribavirin is used in HFRS (Hantaan virus) with some success in decreasing the severity of the kidney injury. Its effectiveness in HPS, however, is not established. The evidence for the use of corticosteroids in the treatment of severe HFRS and HPS is mostly anecdotal.

**Prognosis**

The outcome is highly variable depending on severity of disease. In Sin Nombre virus infections, the persistence of elevated IgG titers correlates with a favorable outcome.

---

Differential Diagnosis

It may be difficult to distinguish yellow fever from hepatitis, malaria, leptospirosis, louse-borne relapsing fever, dengue, and other hemorrhagic fevers on clinical evidence alone. Albuminuria is a constant feature in yellow fever patients and its presence helps differentiate yellow fever from other viral hepatitis. Serologic confirmation is often needed.

Treatment

No specific antiviral therapy is available. Treatment is directed toward symptomatic relief and management of complications. If not in an endemic area, the patient should be isolated from mosquitoes to prevent transmission, since blood in the acute phase is potentially infectious.

Prognosis

The mortality rate of the severe form is 20–50%, with death occurring most commonly between the sixth and the tenth days. In survivors, the temperature returns to normal by the seventh or eighth day. The prognosis in any individual case is guarded at the onset, since sudden changes for the worse are common. Intractable hiccups, copious black vomitus, melena, anuria, jaundice, and elevated AST are unfavorable signs. Convalescence is prolonged, including 1–2 weeks of asthenia. Infection confers lifelong immunity to those who recover.

Prevention

Transmission is prevented through mosquito control. Live virus vaccine is highly effective and should be provided for immunocompetent persons over 9 months of age living in or traveling to endemic areas. Revaccination is recommended every 10 years for persons with continued exposure. Vaccine-induced reactions—including neurotropic (encephalitis-like syndrome) and viscerotropic (resembling yellow fever; with one space-time cluster of viscerotropic disease among five patients with four deaths reported from Ica, Peru in 2007)—diseases—are reported particularly among patients aged 60 years or older, patients with immune dysfunction or with multiple sclerosis (whose rate of exacerbation in increased 1–5 weeks after vaccination). The aged should probably not be vaccinated and those with immune dysfunction or multiple sclerosis should not be vaccinated, although HIV-infected persons with high CD4 counts safely receive the vaccine with an adverse event rate of about 3%. The safety of the vaccine in pregnant patients is not verified, and pregnant women should, if possible, defer travel to endemic areas (see Chapter 30). Eradication is difficult because of the sylvatic cycle (mainly maintained by non-human primates). Transmission from mother to infant during breastfeeding is documented.

An inactivated, alum-adjuvant vaccine is under development and in phase I studies appears to be safer than the live vaccine and is immunogenic.

The yellow fever virus vaccine shows genetic homology to a melanoma antigen, and in one retrospective study, patients who were given the vaccine showed a reduced risk of melanoma after 10 years.
Related viruses found in Eastern and mid-Western North America are the Powassan agent and the deer tick virus. Increasing prevalence of deer ticks in North America is thought to be responsible for the increased (but still small) number of North American cases of these two serologically indistinguishable viruses.

### Clinical Findings

#### A. Symptoms and Signs

Most cases are subclinical and many resemble a flu-like syndrome. There are two variants of clinical presentation: the Western subtype occurs mainly in the fall and is most severe among the elderly, and the Eastern subtype is more severe among children.

**Western subtype disease** is biphasic in which after 2–10 days of fever (usually with malaise, headache, and myalgias), a 1–21 day symptom-free interval leads to a second phase with resumed fevers followed by neurologic symptoms. **Eastern subtype disease** is progressive without an asymptomatic interval. The neurologic manifestations range from febrile headache (accounting for up to 50% of Eastern subtype cases) to aseptic meningitis and encephalitis with or without myelitis (preferentially of the cervical anterior horn) and spinal paralysis (usually flaccid). A myeloradiculitic form can also develop but is less common. Double infection with *Borrelia burgdorferi* (the agent of Lyme disease; transmitted by the same tick vector) may result in a more severe disease. Homozygosity for a 32bp deletion in the gene coding for the chemokine receptor CCR5, producing its complete loss of function, predisposes to severe disease. Mortality in TBE is usually a consequence of brain edema or bulbar involvement.

#### B. Diagnosis

Leukocytosis and neutrophilia are common. Abnormal cerebrospinal fluid findings include a pleocytosis that may persist for up to 4 months. Neuroimaging shows hyperintense lesions in the thalamus, brainstem, and basal ganglia. TBE virus IgM and IgG are detected by ELISA techniques when neurologic symptoms occur. Cross-reactivity with other flaviviruses or a vaccinated state (see below) may require confirmation by detection of TBE virus–specific antibodies in cerebrospinal fluid. RT-PCR of blood (at earlier stages of the disease) or cerebrospinal fluid can sometimes, if available, assist with the diagnosis. TBE virus can be differentiated from serologically indistinguishable viruses (Powassan agent and deer tick virus) by plaque-reduction neutralization tests.

### Complications

The main sequela of disease is paresis, which occurs in up to 10% of Western and up to 25% of Eastern subtype disease. Other causes of long-term morbidity include protracted cognitive dysfunction and persistent spinal nerve paralysis. The postencephalitic syndrome, characterized by headache, difficulties concentrating, balance disorders, dysphasia, hearing defects, and chronic fatigue, occurs with both subtypes. A progressive motor neuron disease and partial continuous epilepsy are complications seen with the Eastern subtype.

### Differential Diagnosis

The differential diagnosis includes other causes of aseptic meningitis such as enteroviral infections, herpes simplex encephalitis, and a variety of tick-borne pathogens including tularemia, the rickettsial diseases, babesiosis, Lyme disease, poliomyelitis (no longer reported from Eastern Europe) and other flaviviral infections.

### Treatment

Therapy is largely supportive. Some clinicians believe corticosteroids may be useful, although no controlled clinical trials exist.

### Prevention

There are two inactivated TBE virus vaccines for adults and two vaccines for children licensed in Europe. Their effectiveness is about 99% when properly administered. The initial vaccination schedule requires 1 year with boosters every 3–5 years. There are decreased antibody titers and booster response in recipients of TBE vaccines who are over 50 years of age, indicating the need for a modified immunization strategy in older patients. Neuritis and neuropathies of peripheral nerves (plexus neuropathy—paresis of lower limb muscles, polyradiculopathy) are recognized complications of TBE vaccination. Rare cases of olfactory dysfunction are also reported. Other prevention recommendations include avoidance of tick exposure and pasteurization of milk.

---

### References

### 6. Colorado Tick Fever

- **Onset**: 1–19 days (average, 4 days) following tick bite.
- **Fever**, chills, myalgia, headache, prostration.
- **Leukopenia**, thrombocytopenia.
- **Second attack** of fever after remission lasting 2–3 days.
General Considerations

Colorado tick fever is a reportable acute reovirus infection transmitted by *Dermacentor andersoni* tick bite. The disease is limited to the western United States and Canada and is most prevalent during the tick season (March to November). There is a discrete history of tick bite or exposure in 90% of cases. The virus infects the marrow erythrocyte precursors, leading to viremia lasting the life span of the infected red cells. Blood transfusions can be a vehicle of transmission.

Clinical Findings

A. Symptoms and Signs

The incubation period is 3–6 days. The onset is usually abrupt with fever (to 38.9–40.6 °C), sometimes with chills. Severe myalgia, headache, photophobia, anorexia, nausea and vomiting, and generalized weakness are prominent. Physical findings are limited to an occasional faint rash. The acute symptoms resolve within a week. Remission is followed in 50% of cases by recurrent fever and a full recrudescence lasting 2–4 days. In an occasional case, there may be three bouts of fever.

The differential diagnosis includes influenza, Rocky Mountain spotted fever, numerous other viral infections and, in the right setting, relapsing fevers.

B. Laboratory Findings

Leukopenia (2000–3000/mcL) with a shift to the left and atypical lymphocytes occurs, reaching a nadir 5–6 days after the onset of illness. Thrombocytopenia may occur. Viremia can be demonstrated by inoculation of blood into mice or by fluorescent antibody staining of the patient’s red cells (with adsorbed virus). An RT-PCR assay may be used to detect early viremia. Detection of IgM by capture ELISA or plaque reduction neutralization is possible after 2 weeks from symptom onset and is the most frequently used diagnostic tool.

Complications

Aseptic meningitis (particularly in children), encephalitis, and hemorrhagic fever occur rarely. Malaise may last weeks to months. Fatalities are very rare. There is one reported case of spontaneous abortion and multiple congenital anomalies associated with Colorado tick fever infection during pregnancy.

Treatment

No specific treatment is available. Ribavirin has shown efficacy in an animal model. Antipyretics are used, although salicylates should be avoided due to potential bleeding with the thrombocytopenia seen in patients with Colorado tick fever. Tick avoidance is the best prevention.

Prognosis

The disease is usually self-limited and benign.

Prevention

The essence of prevention is vector (tick) control, particularly from March to November.

7. Chikungunya Fever

Chikungunya ("that which bends up" in Bantu) is a flaviviral infection transmitted to humans by *Aedes aegypti* and *Aedes albopictus* (the "Asian tiger mosquito") and is considered a classic "arthrogenic" virus. The virus is indigenous to tropical Africa and Asia with recent outbreaks reported from areas that adjoin the Indian Ocean, Southeast Asia and its neighboring islands (2005–2007), South India (2005) a major outbreak in Reunión Island, but also from Europe including an outbreak in Italy (2007). The attack rates are often as high as 50%. The endemicity of *A aegypti* in the Americas and the introduction of *A albopictus* into Europe and the New World raise the concerns of a global extension of the epidemic. The Rh-negative population appears to be immune. There are reports of cases of Chikungunya coinfection with yellow fever, malaria, and dengue fever.

Clinical Findings

A. Symptoms and Signs

After an incubation period of 1–12 days (average 2–4), there is an abrupt onset of fever; headache; intestinal complaints; myalgias; and arthralgias/arthritis affecting small, large, and axial joints. The simultaneous involvement of more than 10 joints and the presence of tenosynovitis (especially in the wrist) are characteristic. The stooped posture of patients gives the disease its name. Joint symptoms persist for 4 months in 33% and linger for years in about 10%. A centrally distributed pruritic maculopapular rash is reported in 50% of the patients, but it can be bulbous with sloughing in children. Mucosal disease occurs in about 15%. Facial edema and localized petechiae are reported. Neurologic complications, including encephalitis, myelopathy, peripheral neuropathy, myeloneuropathy, and myopathy, are usually associated with a good outcome. Rare cases of mother-to-child transmission at birth are reported. The virus has no observable effect on the outcome of pregnancy. In infants, primary manifestations of disease include fever, lethargy, acrocyanosis, and erythema evolving into vesiculobullous lesions. Hemorrhagic fever–like presentations are exceptional. Coinfection with other respiratory viruses, in particular dengue, is common. Death is rare and usually related to underlying comorbidities.

B. Laboratory Findings

Diagnosis is made epidemiologically and clinically. Mild leukopenia occurs as does thrombocytopenia, which is seldom severe. Elevated inflammatory markers do not correlate well with the severity of arthritis. Radiographs of affected joints are normal.
RSV is a major cause of morbidity and mortality at the extremes of age.
- Care for patients with RSV infections is largely supportive.
- A monoclonal antibody against RSV, palivizumab, is good but expensive prophylaxis among patients with certain at-risk cardiopulmonary conditions.
- No active vaccination for RSV is available to date.

General Considerations
Respiratory syncytial virus (RSV) is a paramyxovirus that causes annual outbreaks during the wintertime with usual onset of pulmonary symptoms between mid October and early January in the United States (excluding Florida). There are two major subtypes, A and B. RSV is the leading cause of hospitalization in US children, with annual hospitalization rates of 17 per 1000 children under 6 months and 3 per 1000 children under 5 years of age. Risk factors for infection in children include prematurity, low birth weight, younger age (especially younger than 6 months), bronchopulmonary dysplasia, congenital heart disease, lower birth order, and day care exposure. RSV infection in children is associated with persistence of airway reactivity later in life.

RSV also causes upper and lower respiratory tract infection in adults with increased severity in the elderly, persons with severe combined immunodeficiency, and following lung or bone marrow transplantation (because CD8 T cells are not available for viral clearance). Recurrent infections occur throughout life. The virus enters through contact with mucosal surfaces. The average incubation period is 5 days.

In immunocompromised patients, such as bone marrow transplant recipients, serious pneumonia can occur and outbreaks with a high mortality rate (> 70%) are reported.

Other paramyxoviruses important in human disease include human metapneumovirus, parainfluenza virus, and Nipah virus.

Human metapneumovirus is less common and less pathogenic than RSV and is mainly a seasonal virus circulating during late winter to early spring. It is divided into subgroups A and B. Clinical presentations include mild upper respiratory tract infections to severe lower respiratory tract infections (eg, bronchiolitis, croup, and pneumonia) among slightly older children and lower respiratory tract (sometimes severe) infections among immunocompromised and elderly adults. In lung transplant recipients, human metapneumovirus is a common cause of respiratory illness and is thought to increase the risk of acute and chronic graft rejection.

Human parainfluenza viruses (HPIVs) are commonly seen in children and are the most common cause of laryngotracheitis (croup). Four different serotypes are described, and they differ in their clinical presentations as well as epidemiology. HPIV-1 and HPIV-2 are responsible for croup. HPIV-3 is associated with bronchiolitis and pneumonia. HPIV-4 is a less frequently reported pathogen. Reinfections are common throughout life. HPIVs can also cause severe disease in the elderly, immunocompromised persons, and those with chronic illnesses.

Nipah virus, is a highly virulent paramyxovirus first described in 1999. Cases are concentrated mainly in Southeast Asia (Malaysia, Singapore, Bangladesh and India). Fruit bats are identified as the natural host of the virus. Direct pig-human, cow-human, human-human, and nosocomial transmission are reported. Nipah virus causes acute encephalitis with a high fatality rate (67–92%), although respiratory symptoms are also described. Cranial nerves palsies, encephalopathy, and dysoria are among neurologic sequelae (15–32%) seen on infected individuals. Relapses occurring weeks and months after initial infection are described (3.4–7.5%).

Bocavirus infections are discussed under Erythrovirus (parvovirus) infections below.

Clinical Findings
A. Symptoms and Signs
In RSV bronchiolitis, proliferation and necrosis of bronchiolar epithelium develop, producing obstruction from
sloughed epithelium and increased mucus secretion. Signs include low-grade fever, tachypnea, and wheezes. Apnea is a common presenting symptom. Hyperinflated lungs, decreased gas exchange, and increased work of breathing are present. In children, RSV is globally the most common cause of acute lower respiratory infection and also a common cause of acute and recurrent otitis media. In patients with Down syndrome, RSV develops at a later age and is associated with more protracted hospitalizations.

**B. Laboratory Findings**

A rapid diagnosis of RSV infection is made by viral antigen identification of nasal washings using an ELISA or immunofluorescent assay. Culture of nasopharyngeal or lower respiratory tract secretions remain the standard of diagnosis, although PCR is increasingly used. Coinfection with bacteria is relatively uncommon in industrialized countries. Coinfection with *B. pertussis* and other viruses occurs in a subset of patients hospitalized for RSV infection. Detection of parainfluenza virus usually requires culture, but tests for rapid detection of viral antigens with immunofluorescence or ELISA, and PCR techniques are also available. Human metapneumovirus is best diagnosed by PCR. ELISA (serum and cerebrospinal fluid) and PCR (urine, respiratory secretions but not blood) are both used for Nipah virus infection diagnosis.

**Treatment & Prevention**

Treatment of RSV consists of supportive care, including hydration, humidification of inspired air, and ventilatory support as needed. Neither bronchodilating agents nor corticosteroids have demonstrated efficacy in bronchiolitis although individual patients with significant bronchospasm or history of asthma might respond to them.

The use of nebulized or intravenous ribavirin can be considered in high-risk patients, such as those with a history of bone marrow transplantation, although it is of limited benefit. Pregnant women, including hospital staff, should avoid ribavirin exposure. Therapy with surfactant lacks evidence to make recommendations on its use. In the United States, RSV immunoglobulin G is no longer available and has been replaced with palivizumab, a monoclonal RSV antibody. Prophylactic administration of palivizumab (15 mg/kg intramuscularly monthly during the season of high transmission) is recommended for infants with high-risk factors, such as chronic lung disease of prematurity and congenital heart disease. Future studies may entail the use of small inhibitory RNA molecules and of new monoclonal antibodies under development, such as motavizumab (awaiting FDA approval).

No RSV vaccine is licensed to date; a past formalin-inactivated RSV vaccine was complicated with adverse outcomes and was discontinued. A phase-1 study of a live attenuated RSV given with the parainfluenza virus type 3 vaccine is promising with good seroresponse and safety profile. Other vaccine attempts have included live attenuated vaccines (which failed to show significant clinical protection or immunogenicity), protein subunit vaccines, and live viral vector vaccines (all with limited data). The use of RNA interference therapy in lung transplant patients may have some beneficial effects.

Prevention in hospitals entails rapid diagnosis, handwashing, contact isolation, and perhaps passive immunization. The use of conjugated pneumococcal vaccination appears to decrease the incidence of concomitant pneumonia associated with viral infections in children in some countries.

Therapeutic modalities for human metapneumovirus and parainfluenza virus infections under investigation include intravenous ribavirin administration. During the initial Nipah virus outbreak, ribavirin was used empirically, although its efficacy remains questionable. Humanized monoclonal antibodies used in animal models show promising results.

**2. Seasonal Influenza**

**ESSENTIALS OF DIAGNOSIS**

- Cases usually in epidemic pattern.
- Abrupt onset with fever, chills, malaise, cough, coryza, and myalgias.
- Aching, fever, and prostration out of proportion to catarrhal symptoms.
- Leukopenia.

**General Considerations**

Influenza (an orthomyxovirus) is a highly contagious disease transmitted by the respiratory route. Transmission occurs primarily by droplet nuclei rather than fomites or direct contact. There are three types of influenza viruses. While type A can infect a variety of mammals (humans, swine, horses, etc) and birds, types B and C almost exclusively infect humans. Type A viruses are further divided into subtypes based on the hemagglutinin (H) and the
neuraminidase (N) expressed in their surface. There are 16 subtypes of hemagglutinin and 9 subtypes of neuraminidase. Annual epidemics usually appear in the fall or winter (although sporadic cases occur as summer outbreaks in northern areas such as Alaska or the southern hemisphere). Epidemics affect 10–20% of the global population on average each year and are typically the result of frequent minor antigenic variations of the virus, or antigenic drift, which are more common in influenza A virus. On the other hand, pandemics—associated with higher mortality—appear at longer and varying intervals (decades) as a consequence of a major genetic reassortment of the virus (antigenic shift) or the mutation of an animal virus that adapts to the human (as with the pandemic virus of 1918 with H1N1 properties).

Currently, the main circulating seasonal influenza viruses are the human–origin A (H3N2) subtype (seasonal H1N1 is no longer widely prevalent), as well as two lineages of type B. A highly pathogenic avian (H5N1) subtype that caused occasional human infections in Asia, Africa (Egypt), and Europe over the last decade is of continued global concern. The novel swine-origin influenza A (pandemic H1N1) virus, which emerged in Mexico in March of 2009 and quickly spread through North America, is of particular concern for pregnant women and immunosuppressed persons. Infections due to avian-origin and the 2009 H1N1 viruses are covered in the next sections.

► Clinical Findings

A. Symptoms and Signs

Seasonal influenza viruses of antigenic types A and B produce clinically indistinguishable infections, whereas type C usually causes a minor illness. The incubation period is 1–4 days. In unvaccinated persons, uncomplicated influenza often begins abruptly. Symptoms include fever, chills, malaise, myalgias, substernal soreness, headache, nasal stuffiness, and occasionally nausea. Fever lasts 1–7 days (usually 3–5). Coryza, nonproductive cough, and sore throat are present. Elderly patients may present with only lassitude and confusion, often without fever or respiratory symptoms. Signs include mild pharyngeal injection, flushed face, and conjunctival redness. Moderate enlargement of the cervical lymph nodes may be observed. The presence of fever (> to 38.2°C) and cough during influenza season is highly predictive of influenza infection in those older than 4 years of age.

B. Laboratory Findings

Leukopenia is common, but leukocytosis can occur. Proteinuria may be present. The virus may be isolated from throat swabs or nasal washings by inoculation of embryonated eggs or cell cultures. Rapid immunofluorescence assays and enzyme immunoassays for detection of influenza antigens from nasal or throat swabs are becoming widely available. The sensitivity of such assays is suboptimal (60–80%) and only a few can distinguish between influenza A and B. More sensitive nucleic acid (PCR) techniques are increasingly accessible. Complement-fixing and hemagglutination-inhibiting antibodies appear during the second week. Microarrays may be used in the future to monitor the spread of pathogenic viral variants.

► Complications

Influenza causes necrosis of the respiratory epithelium, which predisposes to secondary bacterial infections. In turn, bacterial enzymes (eg, proteases, trypsin-like compounds, and streptokinase) activate influenza viruses. Frequent complications are acute sinusitis, otitis media, purulent bronchitis, and pneumonia. Children under 5 years of age, pregnant women, residents of nursing homes and long-term care facilities, the elderly (aged 65 years or older), children and teens under 19 years of age who are receiving long-term aspirin therapy, and persons with underlying medical conditions (pulmonary, renal, cardiovascular, hepatic, hematologic, neurologic and neurodevelopmental conditions and immune-deficient conditions such as HIV) are at high risk for complications. Persons who are morbidly obese (body mass index > 40), American Indians, and Alaskan natives are also at high risk for complications.

Primary influenza pneumonia may occur, particularly in young children with cardiovascular disease and pregnant women, and is associated with a high mortality. Secondary bacterial pneumonia due to pneumococci, staphylococci, or Haemophilus spp is common. Pneumococci and mycoplasma occur rarely. There is an association of acute myocardial infarction with preceding respiratory infection, including influenza; a UK study showed that influenza vaccination is associated with a lower rate of acute myocardial infarction. Rhabdomyolysis is a rare late complication of influenza.

Reye syndrome (fatty liver with encephalopathy) is a rare and severe complication of influenza (usually B type) and other viral diseases (eg, varicella), particularly in young children. It consists of rapidly progressive hepatic failure and encephalopathy, and there is a 30% mortality rate. The pathogenesis is unknown, but the syndrome is associated with aspirin use in the management of viral infections. Hypoglycemia, elevation of serum aminotransferases and blood ammonia, prolonged prothrombin time, and change in mental status all occur within 2–3 weeks after onset of the viral infection. Histologically, the periphery of liver lobules shows striking fatty infiltration and glycogen depletion. Treatment is supportive and directed toward the management of cerebral edema. Other encephalopathic complications of influenza are uncommon and include an acute necrotizing encephalopathy associated with disseminated intravascular coagulation and cytokine storm, with worsening when treated with certain nonsteroidal anti-inflammatory drugs (diclofenac and mefenamic acid), and an acute encephalopathy associated with febrile seizures and the use of theophylline. Influenza infections are an infrequent trigger of Guillain-Barré syndrome.

► Treatment

Many patients with influenza prefer to rest in bed. Analgesics and a cough mixture may be used. Treatment should be considered for those with a suggestive clinical
presentation or with laboratory confirmed influenza and at high risk for developing complications (nursing home residents; patients with chronic pulmonary, cardiovascular, kidney, or liver disease; those with diabetes mellitus, active malignancy, immunosuppression, or impairment for managing respiratory secretions), or living with persons at significant risk for them. Maximum benefit is expected with the earliest initiation of therapy. Although the benefit of antiviral therapy after 48 hours of illness is reduced, it should be considered if the patient is hospitalized.

The neuraminidase inhibitors, either inhaled zanamivir, 10 mg (2 inhalations) twice daily for 5 days, or oral oseltamivir, 75 mg twice daily for 5 days, are equally effective in the treatment of susceptible strains of influenza. Clinical trials show a reduction in the duration of symptoms as well as secondary complications, such as otitis, sinusitis, or pneumonia, but not in the rate of hospitalizations or mortality when using these agents. When administered early, antiviral medications (neuraminidase inhibitors) are most effective. Since high levels of resistance to the adamantanes (amantadine and rimantadine) persist among 2009 influenza A (H1N1) and A (H3N2) viruses and these agents are not effective against influenza B viruses, adamantanes are generally not recommended for treatment. Resistance to neuraminidase inhibitors (oseltamivir and zanamivir) can occur with prolonged use in immunocompromised patients or in avian (H5N1)-infected patients. High rates (approximately 25%) of oseltamivir resistance in influenza A (H1N1) viruses were reported in surveillance data from several areas in Europe and Africa between 2007 and 2009 associated with a genetic mutation (H275Y) in the neuraminidase protein. With the advent of the pandemic H1N1 strain (below) circulating levels of seasonal H1N1 were so low that resistance to oseltamivir was not a significant problem. Oseltamivir-resistant pandemic H1N1 isolates are reported with the same H275Y mutation that shows zanamivir sensitivity. Since December 2010, there is no evidence that significant neuraminidase resistance is occurring among pandemic H1N1 isolates and resistance among current seasonal influenza A (H1N1), influenza A (H3N2), and influenza B isolates is rare. The association of oseltamivir resistance with possible pneumonia is reported but requires further study.

Zanamivir is relatively contraindicated among persons with asthma because of the risk of bronchospasm and is not formulated for use in mechanically ventilated patients. Transient neuropsychiatric events, occasionally resulting in self-injury and death, have been reported post marketing for both neuraminidase inhibitors. Patients receiving these drugs should be closely monitored for any unusual behavior, and healthcare professionals should be notified immediately if such signs occur. Laninamivir is a long-acting neuraminidase inhibitor used for the treatment of seasonal influenza, including infection caused by oseltamivir-resistant virus. It remains under phase III clinical trials in America but is licensed in Japan. Ribavirin (unlabeled usage, 1.1 g/d, diluted to 20 mg/mL, delivered as small particle aerosol with oxygen over 12–18 hours a day for 3–7 days (see Table 32–1)) may be effective in severely ill patients with influenza A or B. In vivo studies often do not mimic efficacy in vitro.

The neuraminidase inhibitor, peramivir, is indicated for intravenous use in patients with 2009 H1N1 (available through the CDC’s Emergency Use Authorization).

Antibacterial antibiotics should be reserved for treatment of bacterial complications. Acetaminophen or ibuprofen rather than aspirin should be used for fever in children.

**Prognosis**

The duration of the uncomplicated illness is 1–7 days, and the prognosis is excellent in healthy, nonelderly adults. Purulent bronchitis and bronchiectasis may result in chronic pulmonary disease and fibrosis that persist throughout life. Most fatalities are due to bacterial pneumonia although exacerbations of other diseases processes, in particular cardiac diseases, occur which contributed to the overall increase in fatalities. Influenza pneumonia has a high mortality rate among pregnant women and persons with a history of rheumatic heart disease. Current mortality is low except in debilitated individuals.

If the fever recurs or persists for more than 4 days with productive cough and white cell count over 10,000/mcL, secondary bacterial infection should be suspected. Pneumococcal pneumonia is the most common secondary infection, and staphylococcal pneumonia is the most serious.

**Prevention**

Annual administration of influenza vaccine is the most effective measure for preventing influenza and its complications. Vaccines available for use in the United States are the FDA-approved trivalent inactivated influenza vaccine (TIV) and the trivalent live attenuated influenza vaccine (LAIV). They both contain antigens from 1 strain each of pandemic influenza A (H1N1), influenza A (H3N2), and influenza B. All persons 6 months of age are greater are recommended to receive annual influenza vaccination.

The Centers for Disease Control and Prevention and the American College of Obstetricians and Gynecologists’ Committee recommend influenza vaccination for all women who will be pregnant through the influenza season (October through May in the United States) and vaccination early in the season regardless of gestational age. No study to date has shown any adverse consequence of inactivated influenza vaccine in pregnant women or their offspring. The FDA has approved Fluzone High-Dose, a TIV containing four-times more hemagglutinin than standard TIV, for persons age 65 or older as well as Fluzone intradermal trivalent vaccine (15 mcg hemagglutinin per strain) which is now commercially available. The intradermal vaccine is equally immunogenic and safe but more expensive than the traditional intramuscular vaccine.

The LAIV is available for use in healthy individuals between 2 and 49 years of age; it should not be given to adult women who are pregnant. For children, LAIV shows superior efficacy over TIV.

The seasonal influenza vaccines can reduce influenza hospitalizations by an estimated 61%.
All of these vaccines are contraindicated in persons with well-substantiated hypersensitivity to chicken eggs or other components of the vaccine (skin testing can be performed by an allergist), in persons with a history of Guillain-Barré syndrome, or in persons with an acute febrile illness until symptomatic improvement. Concomitant warfarin or corticosteroid therapy is not a contraindication to influenza vaccination. Side effects are infrequent and include tenderness, redness, or induration at the intramuscular site of the TIV and mild upper respiratory symptoms for the LAIV.

Chemoprophylaxis is considered for individuals when vaccination is contraindicated and in those exposed to an infected patient within 2 weeks after vaccination with TIV. It is not necessary and is contraindicated with the LAIV, since this vaccine confers more rapid protection. Other circumstances that warrant consideration of chemoprophylaxis include outbreaks in long-term–care facilities, persons living with or in close contact with high-risk individuals, persons with immune deficiencies who might not respond to vaccination, unvaccinated staff during response to an outbreak in a closed institutional setting with residents at high risk, and first responders to epidemic situations.

Chemoprophylaxis against influenza A and B is traditionally accomplished with a single daily dose of the neuraminidase inhibitors oseltamivir (75 mg/d, oral) or zanamivir (10 mg/d, inhaled). These agents reduce the attack rate among unvaccinated individuals if begun within 48 hours after exposure. The CDC recommends chemoprophylaxis for 7 days after exposure. For outbreak control in long-term–care facilities and hospitals, a minimum of 2 weeks is recommended, including in vaccinated persons, and until 1 week after identification of the last known case. Zanamivir should not be given as chemoprophylaxis to asthmatic persons, nursing home residents, or children under 5 years of age. Hand hygiene and surgical facemasks appear to prevent household transmission of influenza virus isolates when implemented within 36 hours of recognition of symptoms in an index patient. Such nonpharmaceutical interventions assist in mitigating the spread of pandemic and interpandemic influenza to nonvaccinated persons. Vaccination remains the mainstay of prevention.

3. Avian Influenza (H5N1)

The normal hosts for avian influenza viruses are aquatic fowl. Although avian influenza was first recognized in Italy in 1878, the current outbreak of highly pathogenic influenza A subtype (H5N1) in poultry was recognized in 1997 in Hong Kong and was followed by the first documented human cases. A massive slaughter of poultry was attempted to contain the disease. Outbreaks of H5N1 influenza in poultry emerged in 2003 and now involve more than 65 countries of East and Southeast Asia, Eurasia, Western and Eastern Europe, Northern Africa, and Haiti. The 562 confirmed human cases as of October 2011 include 332 deaths (79% of cases and 78% of deaths are confirmed influenza-associated hospitalizations in community dwelling older adults. J Infect Dis. 2011 Feb 15;203(4):500–8. [PMID: 21220776]

Thorstlund K et al. Systematic review of influenza resistance to the neuraminidase inhibitors. BMC Infect Dis. 2011 May 19;11:134. [PMID: 21592407]

Clinical Findings

A. Symptoms and Signs

Distinguishing avian influenza from regular influenza is difficult. History of exposure to dead or ill poultry in the prior 10 days, recent travel to Southeast Asia or Egypt, or contact with known cases should be investigated. The symptoms and signs include predominantly respiratory symptoms (cough and dyspnea), but a variety of other systems may be involved, producing headaches and gastrointestinal complaints in particular. Subclinical disease is relatively rare. With cytokines responsible for much of the pathology, prolonged febrile states and generalized malaise are common. Children are preferentially impacted. Respiratory failure is the usual cause of death.

B. Laboratory Findings

Current commercial rapid antigen tests are not optimally sensitive or specific for detection of H5N1 influenza but are still first-line diagnostic tests because of their widespread availability. Diagnostic yield can be improved by early collection of samples. More sensitive RT-PCR assays are available through many hospitals and state health departments. An initial negative result in the right clinical setting warrants retesting. Throat or lower respiratory swabs may provide higher yield of detection than nasal swabs. When highly pathogenic strains (eg, H5N1) are suspected, extreme care in the handling of these samples must be observed during preliminary testing. Positive samples must then be forwarded to the appropriate public health authorities for further investigations (eg, culture) in laboratories with the adequate level of biosafety (level 3).

Treatment

Resistance of avian H5N1 influenza strains to amantadine and rimantadine is present in most geographic areas. The current first-line recommendation is to use the neuraminidase inhibitor oseltamivir, 75 mg orally twice daily for 5 days administered within 48 hours from onset of illness. Overall oseltamivir, by modeling, is associated with a 49% reduction in mortality from H5N1 infections. A higher dose (150 mg twice daily), longer duration (7–10 days), and possible combination therapy with amantadine or rimantadine (in countries where A [H5N1] viruses are likely to be susceptible to adamantanes) may be considered in patients with pneumonia or progressive disease. Evidence of resistance to oseltamivir is reported. Although inhaled zanamivir is proven effective in treating seasonal influenza, no data of its efficacy against H5N1 strains are available. Therapy should still be considered for patients when severe avian influenza disease persists after several days of onset. Parenteral treatment with unapproved (but under study) parenteral peramivir or zanamivir preparations may be considered.

Prevention

Postexposure prophylaxis with 75 mg of oseltamivir orally once daily for 7–10 days should be given to household contacts of documented cases. Personnel exposed to patients should be monitored for symptoms. Careful surveillance for human cases and prudent stockpiling of medications with establishment of an infrastructure for dissemination are essential modalities of control. Nonpharmacologic means of control include masks, social distancing, quarantine, travel limitations, and infrastructure development, particularly for emergency departments.

A human vaccine against H5N1 influenza is licensed (but not marketed) in the United States with the government stockpiling supplies in the event of need. This vaccine does not contain adjuvant and as a result, its immunogenicity is only modest. A vaccine with oil-in-water emulsion-based adjuvant is available in Europe. Several other vaccine candidates are undergoing clinical trials. A major concern with H5N1 vaccinology is the evolution of the virus in vaccinated poultry, especially in the endemic nations of Egypt and Indonesia, and the need to maintain current surveillance and update vaccine development should avian influenza become more pathogenic in humans. Seasonal and H5N1 vaccines are given together safely in preliminary studies. Prevention of exposure to avian influenza strains also includes hygienic practices during handling of poultry products, including hand-washing and prevention of cross-contamination, as well as thorough cooking of poultry products (to 70°C). There is no risk of acquiring avian influenza through the consumption of poultry products, although there is a risk associated with handling feathers or birds from endemic areas, and the US government bans the importation of poultry from infected areas.
4. 2009 Pandemic H1N1 Influenza (“A(H1N1)pdm09”)

**ESSENTIALS OF DIAGNOSIS**

- Influenza-like illness with consistent epidemiologic background.
- Respiratory swab allows local screen and more specific analysis by state public health laboratories.

**General Considerations**

An outbreak of swine-origin (H1N1) influenza virus (formerly Swine-Origin Influenza Virus [S-OIV] or H1N1/A/California/04/2009, currently “A(H1N1)pdm09”) emerged in Mexico City in March 2009. After initially spreading in the United States and Canada, the virus spread globally with cases reported from over 40 nations by mid-2009. The World Health Organization declared a pandemic on June 11, 2009 which lasted until August 10, 2010. This was the first pandemic since 1968 with circulation outside the usual influenza season in the Northern Hemisphere. The 2009 H1N1 influenza virus has replaced seasonal A (H1N1) and will presumably continue to spread for years to come, akin to the seasonal influenza virus. This virus originates from triple-reassortment North American swine, human and avian virus lineages and Eurasian swine virus lineages.

**Clinical Findings**

**A. Symptoms and Signs**

This pandemic strain of H1N1 causes a broad range of clinical symptoms ranging from typical symptoms (fever, malaise, myalgias, cough, sore throat, rhinorrhea, shortness of breath) commonly accompanied by gastrointestinal manifestations (especially diarrhea) to fulminant viral pneumonia. The principal clinical syndrome leading to hospitalization and ICU admission is diffuse viral pneumonitis with severe hypoxemia and sometimes shock and renal failure. Neurologic complications, including seizures and encephalopathy, and cardiac dysfunction, including myocarditis and pulmonary thromboemboli, have occurred. Cases with pandemic H1N1 associated hemophagocytic syndrome are reported. Most patients with mild disease make full recovery, but 9–31% of hospitalized cases require ICU admission, where the mortality ranges between 14% and 46%. The disease has an incubation period of 1.5 to 7 days.

Attack rates are highest in children and young adults, particularly Hispanics, blacks, and native Americans, with relative sparing of adults older than 60 years of age presumably due to previous exposure with related strains (conferring some degree of cross-protection). High-risk groups include patients with severe obesity, immunosuppression, or neurologic disorders, and especially pregnant and postpartum women. Infection during pregnancy may be associated with severe illness, sepsis, pneumothorax and respiratory failure, spontaneous abortion, preterm labor, and fetal distress. Overall case fatality rate is < 0.5% with 90% of deaths in those under 65 years of age and higher mortality recognized among men and patients with liver disease or a cancer diagnosis within the last year.

**B. Laboratory Findings**

Laboratory findings may include normal to low leukocyte counts with lymphocytopenia and elevated amnontransferases. Elevated alkaline phosphatase, creatine kinase, creatinine, thrombocytopenia and metabolic acidosis suggest poor prognosis. A nasopharyngeal swab, nasal aspirate, combined nasopharyngeal swab with oropharyngeal swab, or material from a bronchoalveolar lavage can be tested for 2009 H1N1. Test material can be kept at 4°C up to 4 days (not frozen) and shipped with an ice pack. Chest radiographic findings are most commonly unremarkable or may show exacerbation of bibasilar markings, but rarely show lobal infiltrates. The CDC or many state public health laboratories can then perform a real-time PCR or viral culture. Local laboratories can perform rapid influenza antigen enzyme or direct immunofluorescent assays to distinguish influenza viruses types A and B, but the results of these assays should be interpreted with caution due to a limited sensitivity (11–70%) and inability to differentiate between seasonal and the 2009 H1N1 influenza viruses.

Pathologic findings in pandemic H1N1 influenza show a particular propensity toward diffuse alveolar damage, akin to the damage seen in patients with avian influenza. This explains the increased risk of the development of ARDS with pandemic H1N1.

**Treatment**

The virus is usually resistant to the adamantanes (amantadine or rimantadine). See the seasonal influenza section for side effects and concerns with these medications.

Treatment entails using neuraminidase inhibitors (oseltamivir or zanamivir; dosages are available in Table 32–1) as early as possible (within 96 hours of onset of symptoms). Early therapy with oseltamivir may reduce duration of hospitalization and progression to severe disease requiring ICU admission or resulting in death. Intravenous formulations of zanamivir and peramivir are available for emergency use in severely ill patients. Oseltamivir-resistant virus is recognized (one cluster of resistant cases is reported from a hospital hematology-oncology ward in North Carolina) and such virus remains sensitive to zanamivir. Person to person transmission with oseltamivir-resistant pandemic H1N1 is documented.

The efficacy of intravenous peramivir is similar to that of oseltamivir but is reduced by a factor of 80 in oseltamivir-resistant 2009 H1N1 viral infection. In such patients, intravenous zanamivir is preferred. While a case of multidrug-resistant pandemic H1N1 virus with resistance to oseltamivir, zanamivir, and peramivir is reported, this particular isolate is less pathogenic in animal studies than standard H1N1 strains. The use of high frequency oscillatory ventilation and extracorporeal membrane oxygenation can improve oxygenation but the impact on mortality in unknown. Corticosteroids for an associated ARDS are
not useful and may increase the mortality with one exception. The use of corticosteroids are associated with a lower rate of mechanical ventilation if they are used in high doses (1 mg/kg prednisone equivalence orally at the time of diagnosis), in patients with a history of hematologic stem cell transplantation.

Updated advice is available at http://www.cdc.gov/h1n1flu/recommendations.htm.

Prevention

The 2011–2012 seasonal influenza vaccines (discussed above) include the A/California/7/2009 (H1N1)–like viral strain and confer protection against 2009 H1N1 influenza. It is especially important that vaccination includes pregnant and unvaccinated postpartum women, household and caregiver contacts of children under 6 months of age, health care and emergency service personnel, healthy persons between 6 months and 24 years of age, and adults 24–64 with underlying medical complications that predispose to influenza (as listed above).

In other areas of the world, monovalent H1N1 vaccines are used. With respect to such pandemic H1N1 vaccines, postmarketing surveillance in China (where 10 different suppliers are used) fails to show any adverse effects or risk for Guillain-Barre syndrome with the vaccine. In another analysis with a monovalent pandemic H1N1 vaccine, the response in elderly patients with asthma was insufficient at the usual 15 mcg; in this group, it is recommended that the dose be increased to 30 mcg (given twice, 30 days apart).

In general, persons with 2009 H1N1 influenza infection should be considered potentially infectious from 1 day before to about 7 days following illness onset. Children and immunosuppressed persons exhibit prolonged viral shedding and may be infectious longer. Any hospital patient in whom the infection is suspected should be isolated in individual rooms with standard and contact precautions plus eye protection.

The World Health Organization guidelines recommend surgical masks for all patient care with the exception of N95 masks for aerosol generating procedures (eg, bronchoscopy, elective intubation, suctioning, administering nebulized medications). For such procedures, an airborne infection isolation room can be used, with air exhausted directly outside or recirculated after filtration by a high efficiency particulate air (HEPA) filter. Strict adherence to hand hygiene with soap and water or an alcohol-based hand sanitizer and immediate removal of gloves and other equipment after contact with respiratory secretions is essential. Precautions should be maintained until 7 days from symptom onset or until the resolution of symptoms, whichever is longer. Postexposure prophylaxis should be considered for close contacts of patients (confirmed, probable, or suspected) who are at high risk for complications of influenza (see section on seasonal influenza) as well as for healthcare personnel, public health workers, or first responders who have had a recognized, unprotected close contact exposure to a person with novel (H1N1) influenza virus infection (confirmed, probable, or suspected) during that person’s infectious period. Despite incomplete data about the safety of neuraminidase inhibitors, the CDC recommends considering postexposure prophylaxis as well in this population.

The MMWR and World Health Organization website provide updates about this pandemic.

5. Severe Acute Respiratory Syndrome (SARS)

ESSENTIALS OF DIAGNOSIS

- Mild, moderate, or severe respiratory illness.
- Travel to endemic area within 10 days before symptom onset, including mainland China, Hong Kong, Singapore, Taiwan, Vietnam, and Toronto.
- Persistent fever; dry cough, dyspnea in most.
- Diagnosis confirmed by antibody testing or isolation of virus.
- No specific treatment; mortality as high as 10% in clinically diagnosed cases.

General Considerations

SARS is a respiratory syndrome caused by an apparently unique coronavirus, transmitted through direct or indirect contact of mucous membranes with infectious respiratory droplets. The virus is shed in stools but the role of fecal-oral transmission is unknown. The natural reservoir appears to be the horseshoe bat (which eats and drops fruits ingested by civets, the earlier presumed reservoir and a likely amplifying host).

The earliest cases were traced to a health care worker in Guangdong Province in China in late 2002, with rapid spread thereafter throughout Asia and Canada, considered a consequence of spread through travel. The 2003 outbreak involved 8098 probable cases from 29 countries, with
Clinical Findings
A. Symptoms and Signs
SARS is an atypical pneumonia that affects persons in all age groups. Severity ranges from asymptomatic disease to severe respiratory illness. Many subclinical cases probably go undiagnosed. Seasonality, as with influenza, is not established. The incubation period is 2–7 days, and it can be spread to contacts of affected patients for 10 days. The mean time from onset of clinical symptoms to hospital admission is 3–5 days. In all clinical cases, persistent fever is present; chills or rigor (or both), cough, shortness of breath, rales, and rhonchi are the rule. Headache, myalgias, and sore throat are common with watery diarrhea occurring in a subset of patients. Elderly patients may report malaise and delirium, without the typical febrile response.

B. Laboratory Findings and Imaging
Leukopenia (particularly lymphopenia) and low-grade disseminated intravascular coagulation are common. Modest elevations of ALT and creatine kinase are frequently seen. Arterial oxygen saturation < 95% with associated nonspecific pulmonary infiltrates is evident in 80% of affected individuals. A high-resolution CT scan is abnormal in 67% of patients with initially normal chest radiographs.

Serum serologies, including enzyme immunoassays and fluorescent antibody assays, are available through public health departments at the state level, although seroconversion may not occur until 3 weeks after the onset of symptoms. The detection rates for the virus using conventional RT-PCR are generally low in the first week of illness. Urine, nasopharyngeal aspirate, and stool specimens are positive in 42%, 68%, and 97%, respectively, on day 14 of illness. Although viral isolation is possible, it is a technically laborious and time-consuming procedure.

Complications
ARDS, with extensive bilateral consolidation, occurs in about 16% patients, and about 20–30% of patients require intubation and mechanical ventilation.

Treatment
Severe cases require intensive supportive management. Different agents including, lopinavir/ritonavir, ribavirin, interferon, IVIG, and systemic corticosteroids were used during the 2003 epidemic, but the treatment efficacy of these agents remains inconclusive. In vitro studies with ribavirin show no activity against the virus, and a retrospective analysis of the epidemic in Toronto suggests worse outcomes in patients who received the drug.

Prognosis
The overall mortality rate of identified cases is about 14%. Poor prognostic factors include advanced age (mortality rate > 50% in those over 65 years of age compared to < 1% for those under 2 years of age), chronic hepatitis B infection treated with lamivudine, high initial or high peak lactate dehydrogenase concentration, high neutrophil count on presentation, diabetes mellitus, acute kidney disease, and low counts of CD4 and CD8 on presentation.

Prevention
Health care workers engaged in procedures that involve contact with respiratory droplets are at risk. Isolation of high-risk patients is essential, and simple hygienic measures may help reduce transmission.

Control measures include quarantining in the home for high-risk exposed persons and the use of facemasks for preventing hospital-acquired infections. The validity of using such masks in the community remains unsubstantiated. Continual reporting of suspected cases is crucial, as is awareness of restrictions on international travel. The most cautious modalities include monitoring for 10 days after the last potential exposure and confinement of recovering patients for a similar interval.

Adenovirus Infections
General Considerations
About a half of the existing adenoviruses (there are over 52 serotypes described to date and divided into 7 subgroups A–G) produce a variety of clinical syndromes. Adenoviruses show a worldwide distribution and occur throughout the year. These infections are usually self-limited or clinically inapparent and most common among infants, young children, and military recruits. However, these infections may cause significant morbidity and mortality in immunocompromised persons, such as HIV-infected persons and COPD patients, as well as in patients who have undergone solid organ and hematopoietic stem cell transplantation or cardiac surgery or in those who have received cancer chemotherapy. A few cases of donor-transmitted adenoviral infection are reported in the past years. Adenoviruses, although a common cause of human disease, also receive particular recognition through their role as vectors in gene therapy.

Clinical Findings
A. Symptoms and Signs
The incubation period is 4–9 days. Clinical syndromes of adenovirus infection, often overlapping, include the following. The common cold (see Chapter 8) is characterized by rhinitis, pharyngitis, and mild malaise without fever.
Nonstreptococcal exudative pharyngitis is characterized by fever lasting 2–12 days and accompanied by malaise and myalgia. Conjunctivitis is often present. Lower respiratory tract infection may occur, including bronchiolitis, suggested by cough and rales, or pneumonia (types 3, 4, and 7 commonly cause acute respiratory disease and atypical pneumonia). Adenovirus type 14 is increasingly reported as a cause of severe and sometimes fatal pneumonia in those with chronic lung disease, but it is also seen in healthy young adults and military recruit outbreaks. Pharyngocconjunctival fever is manifested by fever and malaise, conjunctivitis (often unilateral), mild pharyngitis, and cervical adenitis. Epidemic keratoconjunctivitis (transmissible person to person) occurs in adults and is manifested by bilateral conjunctival redness, pain, tearing, and an enlarged preauricular lymph node (multiple types may be involved in a single outbreak). Keratitis may lead to subepithelial opacities (especially with types 8, 19, or 37). Acute hemorrhagic cystitis is a disorder of children often associated with adenovirus type 11 and 21. Sexually transmitted genitourinary ulcers and urethritis may be caused by types 2, 8, and 37 in particular. Adenoviruses also cause acute gastroenteritis (types 40 and 41), mesenteric adenitis, acute appendicitis, and intussusception. Rarely, they are associated with encephalitis, acute flaccid paralysis, and pericarditis. Adenovirus is commonly identified in endomyocardial tissue of patients with myocarditis and dilated cardiomyopathy. Risk factors associated with severity of infection include youth, chronic underlying infections, recent transplantation, and serotypes 5 or 21.

Hepatitis (type 5 adenovirus), pneumonia, and hemorrhagic cystitis (types 11 and 34) tend to develop in infected liver, lung, or kidney transplant recipients, respectively. Syndromes that may develop in hematopoietic stem cell transplant patients include hepatitis, pneumonia, hemorrhagic cystitis, tubulointerstitial nephritis, colitis, and encephalitis.

B. Laboratory Findings
Antigen detection assays including direct fluorescence assay or enzyme immunoassay are rapid and show sensitivity of 40–60% compared with viral culture (considered the standard). Samples with negative rapid assays require PCR assays or viral cultures for diagnosis. Quantitative real-time rapid-cycle PCR is useful in distinguishing disease from colonization, especially in hematologic cell transplant patients.

► Treatment
Treatment is symptomatic. Ribavirin and cidofovir are used in immunocompromised individuals with occasional success, although cidofovir is attendant with significant renal toxicity and reduced immunosuppression is often required. Adoptive immunotherapy with transfusion of adenovirus-specific T cells is currently being investigated. IVIG is used in immunocompromised patients, but data are still limited. Typing of isolates is useful epidemiologically and in distinguishing transmission from endogenous reactivation. Complications of adenovirus pneumonia in children include bronchiolitis obliterans.

Vaccines are not available for general use. Live oral vaccines containing attenuated type 4 and type 7 were used in military personnel, but they have been discontinued.

OTHER EXANTHEMATOUS VIRAL INFECTIONS

1. Erythrovirus (Parvovirus) Infections
Erythrovirus, formerly parvovirus B19, infects human erythroid precursor cells. It is quite widespread (by age 15 years about 50% of children have detectable IgG) and its transmission occurs through respiratory secretions and saliva, through the placenta (vertical transmission with 30–50% of pregnant women nonimmune), and through administration of blood products. The incubation period is 4–14 days. Chronic forms of the infection can occur. Bocavirus, another erythrovirus (parvovirus), is a cause of winter acute respiratory disease in children and adults.

► Clinical Findings
A. Symptoms and Signs
Erythrovirus (parvovirus B19) causes several syndromes and manifests differently in various populations.

1. Children—In children, an exanthematous illness (“fifth disease,” erythema infectiosum) is characterized by a fiery red “slapped cheek” appearance, circumoral pallor, and a subsequent lacy, maculopapular, evanescent rash on the trunk and limbs. Malaise, headache, and pruritus (especially on the palms and soles) occur. Systemic symptoms and fever are mostly abated by the time of rash appearance.

2. Immunocompromised patients—In immunosuppressed patients, including those with HIV infection or transplanted organs, or with hematologic conditions such as sickle cell disease, transient aplastic crisis and pure red blood cell aplasia may occur. Bone marrow aspirates reveal absence of mature erythroid precursors and characteristic giant pronormoblasts.

3. Adults—A limited nonerosive symmetric polyarthritis that mimics lupus erythematosus and rheumatoid arthritis, which may in some cases be a type II mixed cryoglobulinemia, can develop in middle-aged persons (especially women) but can also occur in children. Rashes, especially facial, are less common in adults.

Chloroquine and its derivatives exacerbate erythrovirus (parvovirus)-associated anemia and are linked with significantly lower hematocrit in hospital admissions in malaria
endemic areas. Rare reported presentations include myocarditis with infarction, constrictive pericarditis, chronic dilated cardiomyopathy, hepatitis, pneumonitis, neutropenia, thrombocytopenia, a lupus-like syndrome, glomerulopathy, CNS vasculitis, and a chronic fatigue syndrome. A subclinical infection is documented among patients with sickle cell disease. Other CNS manifestations of erythrovirus (parvovirus) include encephalitis, meningitis, stroke (usually in sickle cell anemia patients with aplastic crises), and peripheral neuropathy (brachial plexitis and carpal tunnel syndrome) with occasional chronic residua.

The symptoms of erythrovirus (parvovirus) infection can mimic those of autoimmune states such as lupus, systemic sclerosis, antiphospholipid syndrome, or vasculitis. The molecular mimicry of erythrovirus (parvovirus) to human cytokeratin and transcription factors engaged in hematopoesis is the basis for theories that implicate erythrovirus (parvovirus) in the pathogenesis of these autoimmune states.

In pregnancy, premature labor, hydrops fetalis, and fetal loss are reported sequelae. Pregnant women with a recent exposure or with suggestive symptoms should be tested for the disease and carefully monitored if results are positive.

B. Laboratory Findings

The diagnosis is clinical (Table 32–2) but may be confirmed by an elevated titer of IgM anti-erythrovirus (parvovirus) anti-bodies in serum or with PCR in serum or bone marrow. Autoimmune antibodies (antiphospholipid and anti-neutrophil cytoplasmic antibodies) can be present and are thought to be a consequence of molecular mimicry.

Complications

Uncommon complications include the CNS diseases listed above, chronic hemolytic anemia, thrombotic thrombocytopenic purpuric syndrome, acute postinfectious glomerulonephritis, and hepatitis.

Treatment

Treatment in healthy persons is symptomatic (nonsteroidal anti-inflammatory drugs are used to treat arthralgias, and transfusions are used to treat transient aplastic crises). In immunosuppressed patients, IVIG can aid in the reduction of anemia. IVIG does not reduce the complications associated with encephalitis related to erythrovirus (parvovirus). Intrauterine blood transfusion can be considered in severe fetal anemia.

Prevention & Prognosis

Several nosocomial outbreaks are documented. In these cases, standard containment guidelines, including hand-washing after patient exposure and avoiding contact with pregnant women are paramount.

The prognosis is generally excellent in immunocompetent individuals. In immunosuppressed patients, persistent anemia may require prolonged transfusion dependence. Remission of erythrovirus (parvovirus) infection in AIDS patients may occur with HAART, though the immune restoration syndrome is also reported.

2. Poxvirus Infections

Among the nine poxviruses causing disease in humans, the following are the most clinically important: variola/vaccinia, molluscum contagiosum, orf and paravaccinia, and monkeypox.

1. Variola/vaccinia—Smallpox (variola) was a highly contagious disease associated with high mortality and disabling sequelae. Its manifestations include severe headache, acute onset of fever, prostration and a rash characterized by the uniform progression from macules to papules to firm, deep-seated vesicles or pustules. The synchronous progression in smallpox readily differentiates lesions from those of varicella (see also Chapter 6).

Complications of smallpox include bacterial superinfections (cellulitis and pneumonia), encephalitis, and keratitis with corneal ulcerations (risk factor for blindness). Effective vaccination led to its global elimination by 1979 and routine vaccination stopped in 1985. Despite the recommendation of destroying remaining samples of this virus, significant concern exists for the potential misuse of these repositories in military or terrorist activities.

Smallpox should be considered, in concordance with the CDC’s Smallpox Response Plan (www.bt.cdc.gov/agent/smallpox/response-plan/index.asp), in any patient with fever and a characteristic rash (see above) for which other etiologies—such as herpes infections, erythema multiforme, drug reactions (eczema herpeticum may be differentiated from suspect smallpox by appropriate serologic stains), or other infections—are unlikely. Rare cases of vaccine-related disease from contact with a smallpox vaccinee, (including sexually transmission) are reported. Two cases of vaccinia infection after contact with oral rabies animal baits (which uses the vaccinia vector) are reported. Patients with suspected infection should be placed in airborne and contact isolation and the official agency contacted (CDC Emergency Preparedness and Response Branch; 770-488-7100). Original smallpox vaccine was crudely manufactured with a significant side-effect profile, including eczema vaccinatum and acute vaccinia syndrome (fatigue, headaches, myalgias, and fever). Subsequent smallpox vaccines had similar side-effect profiles, but myocarditis and pericarditis also developed in

some patients. The most recent vaccine, ACAM2000 (Acambis, Inc) shows similar safety profiles and is currently used by the US military and stockpiled in the event of biologic warfare.

Contraindications to vaccination include immunosuppression, eczema or other dermatitis in the vaccinee or household contacts, allergy to any component of the vaccine, infants younger than 1 year and pregnant or breastfeeding women. According to current recommendation, it is unnecessary for anyone not handling the smallpox vaccine to be vaccinated.

Inoculation of the vaccine in inappropriate sites (eg, eyes) is unfortunately common. Asymptomatic vaccinia viremia can be detected up to 21 days post vaccination and no blood donation should occur during this interval. Cidofovir may be considered for treatment of varicella if no contraindication exists (outlined above), for those involved in the investigation of the outbreak and for healthcare workers caring for those infected with monkeypox. Post exposure vaccination is also advised for documented contacts of infected persons or animals. US federal agencies currently prohibit the importation of African rodents.

Centers for Disease Control and Prevention (CDC). Updated interim CDC guidance for use of smallpox vaccine, cidofovir, and vaccinia immune globulin (VIG) for prevention and treatment in the setting of an outbreak of monkeypox infections. http://www.cdc.gov/necdod/monkeypox/treatment-guidelines.htm

VIRUSES & GASTROENTERITIS

Viruses are responsible for at least 30–40% of cases of infectious diarrhea in the United States. These agents include rotaviruses; caliciviruses, including noroviruses such as Norwalk virus; astroviruses; enteric adenoviruses; and, less often, toroviruses, coronaviruses, picornaviruses (including the Aichi virus), and pestiviruses. Rotaviruses and noroviruses are responsible for most of nonbacterial cases of gastroenteritis.

Rotaviruses are the leading worldwide cause of dehydrating gastroenteritis in young children and are associated with significant morbidity and mortality (at least 500,000 children under 5 years of age annually from rotavirus infection). Children aged 6 months to 2 years are the most affected, although adults are affected occasionally as well. By age 5, virtually every child has been infected with this pathogen. The diverse set of rotaviruses...
(classified by glycoproteins and protease-sensitive proteins [G-type and P-type antigens] which segregate independently) results in a constellation of phenotypes although only about four of these are responsible for over 90% of disease. Rotavirus infections follow an endemic pattern, especially in the tropics, although they peak during the winter in temperate regions. The virus is transmitted by fecal-oral and can be shed in feces for up to 3 weeks in severe infections. In outbreak settings (eg, daycare centers), the virus is ubiquitously found in the environment, and secondary attack rates are between 16% and 30% (including household contacts). The disease is usually mild and self-limiting. A 2- to 3-day pro- drome of fever and vomiting is followed by nonbloody diarrhea (up to 10–20 bowel movements per day) lasting for 1–4 days. The method of choice for diagnosis is PCR of the stool. It is thought that rarely systemic disease occurs. Treatment is largely symptomatic, with fluid and electrolyte replacement. A trial with nitazoxanide was attendant with moderate success among a small cohort of patients with gastroenteritis from Egypt with efficacy in both the rotavirus and norovirus subgroups. The enkephalinase inhibitor racecadotril (also known as acemorphan, given 1.5 mg/kg every 8 hours orally) is available in many countries (but not the United States), and in a meta-analysis appears to be clinically effective in reducing diarrheal symptoms. Local intestinal immunity gives protection against successive infection.

Two oral rotavirus vaccines are available in the United States: pentavalent human-bovine reassortment rotavirus vaccine (PRV, RotaTeq; to be given at 2, 4, and 6 months of age) and attenuated human rotavirus vaccine (HRV, Rotarix; to be given at 2 and 4 months of age). Contraindications include allergy to any of the vaccine ingredients, previous allergic reaction to the vaccine, and immunodeficiency. The risk of intussusception, which is far lower with this than earlier rotavirus preparations, is small (1:51,000 to 1:68,000 vaccinated infants) and is considered significantly lower than the risk associated with untreated rotavirus gastroenteritis.

Noroviruses, such as Norwalk virus (one of a variety of small round viruses divided into 3 genogroups and at least 25 genotypes), are the major cause of epidemic gastroenteritis. They are responsible for a significant percentage of childhood hospitalizations for gastroenteritis in the developing world (15% in surveys from India, 31% from Peru). They appear to evolve by antigenic drift (similar to influenza). While 90% of young adults show serologic evidence of past infection, no long-lasting protective immunity develops and reinfections are common. In the United States, noroviruses are responsible for over 90% of reported nonbacterial gastroenteritis outbreaks during cold weather intervals (hence the colloquial name “gastric flu”). Outbreak environments include restaurants, long-term care facilities, hospitals, schools, daycare centers, vacation destinations (including cruise ships), and Middle Eastern military bases deployed abroad. Persons at particular risk are the young, the elderly, the institutionalized, and the immunosuppressed. Although transmission is usually fecal-oral, airborne and waterborne transmission are also documented. A short incubation period (24–48 hours), a short symptomatic illness (12–60 hours, but up to 5 days in hospital-associated cases and in children under 11 years of age), a high frequency (> 50%) of vomiting, and absence of bacterial pathogens in stool samples are highly predictive of norovirus gastroenteritis. RT-PCR of stool samples is used for epidemiologic purposes. Treatment is largely symptomatic.

Outbreak control for both rotavirus and norovirus infections include strict adherence to general hygienic measures. Despite the promise of alcohol-based sanitizers for the control of pathogen transmission, such cleansers may be relatively ineffective against the noroviruses compared with antibacterial soap and water, reinforcing the need for new hygienic agents against this prevalent group of viruses. Cohorting of sick patients, contact precautions for symptomatic hospitalized patients, exclusion from work of symptomatic staff until symptom resolution (or 48–72 h after this for norovirus disease), and proper decontamination procedures are crucial.

The reports of efficacy with nitazoxanide or racecadotril in acute gastroenteritis suggest that new avenues of therapy may become more widely available in the future. Vaccine developments are attendant with the complications associated with the rapid evolution (“antigenic drift”) of noroviruses and the probable need for annual strain selection to match circulating variants.

**ENTEROVIRUSES THAT PRODUCE SEVERAL SYNDROMES**

The most famous enterovirus, the poliomyelitis virus, is discussed above under Vaccine Preventable Diseases. Other clinically relevant enteroviral infections are discussed in this section.

### 1. Coxsackievirus Infections

Coxsackievirus infections cause several clinical syndromes. As with other enteroviruses, infections are most common during the summer. Two groups, A and B, are defined either serologically or by mouse bioassay. There are more than 30 serotypes.

---

**REFERENCES**
Clinical Findings

A. Symptoms and Signs

The clinical syndromes associated with coxsackievirus infection are summer grippe; herpangina; epidemic pleurodynia; aseptic meningitis and other neurologic syndromes; acute nonspecific pericarditis; myocarditis; hand, foot, and mouth disease; epidemic conjunctivitis; and other syndromes.

1. Summer grippe (A and B)—A febrile illness, principally of children, summer grippe usually lasts 1–4 days. Minor symptoms of upper respiratory tract infection are often present.

2. Herpangina (A2–6, 10: B3)—There is sudden onset of fever, which may be as high as 40.6 °C, sometimes with febrile convulsions. Other symptoms are headache, myalgia, and vomiting. The sore throat is characterized early by petechiae or papules on the soft palate that ulcerate in about 3 days and then heal. An outbreak in Taiwan with A2 was associated with herpangina and coincided with an enterovirus 71 (below) outbreak, characterized by hand, foot, and mouth disease. Treatment is symptomatic.

3. Epidemic pleurodynia (Bornholm disease) (B1–5)—Pleuritic pain is prominent. Tenderness, hyperesthesia, and muscle swelling are present over the area of diaphragmatic attachment. Other findings include headache, sore throat, malaise, nausea, and fever. Orchitis and aseptic meningitis occur in < 10% of patients. Most patients are ill for 4–6 days.

4. Aseptic meningitis (A and B) and other neurologic syndromes—Fever, headache, nausea, vomiting, stiff neck, drowsiness, and cerebrospinal fluid lymphocytosis without chemical abnormalities may occur, and pediatric clusters of group B (especially B5) meningitis are reported. Focal encephalitis and transverse myelitis are reported with coxsackievirus group A. Disseminated encephalitis occurs after group B infection, and acute flaccid paralysis is reported with both coxsackievirus group A and B. An outbreak of aseptic meningitis occurred in central China (Gansu Province) in 2008, with 85 cases reported of coxsackievirus A9 infection. Severe neonatal illnesses are reported with B1 infections, including encephalomyocarditis and neonatal deaths due to multiorgan failure.

5. Acute nonspecific pericarditis (B types)—Sudden onset of anterior chest pain, often worse with inspiration and in the supine position, is typical. Fever, myalgia, headache, and pericardial friction rub appear early and these symptoms are often transient. Evidence for pericardial effusion on imaging studies is often present, and the occasional patient has a paradoxical pulse. Electrocardiographic evidence of pericarditis is often present. Relapses may occur.

6. Myocarditis (B1–5)—Heart failure in the neonatal period secondary to in utero myocarditis and over 20% of adult cases of myocarditis and dilated cardiomyopathy are associated with group B (especially B3) infections.

7. Hand, foot, and mouth disease (A5, 10, 16)—This disease is sometimes epidemic and is characterized by stomatitis and a vesicular rash on hands and feet. Enterovirus 71 is also a causative agent (see below).

8. Epidemic conjunctivitis—As with enterovirus 70 (see below), the A24 variant of coxsackievirus is associated with acute epidemic hemorrhagic conjunctivitis in tropical areas with outbreaks reported in the last few years in southern China, Pakistan, southern Sudan, and Uganda.

9. Other syndromes associated with coxsackievirus infections—These include rhabdomyolysis, fulminant neonatal hepatitis (occurs rarely), glomerulopathy (group B infections), type 1 diabetes mellitus (mainly group B infections), and thyroid disease (group B4), although definitive causality is not established. A pathogenic role in primary Sjögren syndrome and acute myocardial infarction has also been proposed for group B coxsackievirus infections. A recent report of confirmed infective endocarditis due to coxsackievirus B2 in a patient with a prosthetic cardiac device suggests that viral etiologies of culture-negative infective endocarditis should be considered.

B. Laboratory Findings

Routine laboratory studies show no characteristic abnormalities. Neutralizing antibodies appear during convalescence. The virus may be isolated from throat washings or stools inoculated into suckling mice. Viral culture is expensive, labor demanding, and requires several days for results. A PCR test for enterovirus RNA is available and, although it cannot identify the serotype, it appears to be useful, particularly in cases of meningitis.

Treatment & Prognosis

Treatment is symptomatic. With the exception of meningitis, myocarditis, pericarditis, perhaps diabetes, and rare illnesses such as pancreatitis or polio-like syndrome, the syndromes caused by coxsackieviruses are benign and self-limited. Two controlled trials showed a potential clinical benefit with pleconaril for patients with enteroviral meningitis although the compassionate use of this drug has stopped. There are anecdotal reports of success with IVIG in severe disease.

Echovirus Infections

Echoviruses are enteroviruses that produce several clinical syndromes, particularly in children. Infection is most common during summer. Among reported specimens, death ensues in about 3%. Males younger than 20 years are more commonly infected than other persons.
Over 30 serotypes of echoviruses are recognized and the most common serotypes for disease are types 6, 9, 11, and 30. Most can cause aseptic meningitis, which may be associated with a rubelliform rash. Types 30 and 13 (the latter also associated with meningitis) outbreaks are increasingly reported globally, including a Korean outbreak of the former in 2008, Finland in 2009, and five epidemics of the latter in the United States. An echovirus 4 outbreak of aseptic meningitis occurred in Australia in 2007. A type 18 outbreak in Taiwan in 2006 and another in Missouri in 2007 were associated with childcare. Transmission is primarily fecal–oral. Hand-washing is an effective control measure in outbreaks of aseptic meningitis. Outbreaks related to fecal contamination of water sources, including drinking water and swimming and bathing pools, were reported in the past.

Besides meningitis, other conditions associated with echoviruses range from common respiratory diseases (bronchiolitis occurs often in children) and epidemic diarrhea to myocarditis, a hemorrhagic obstetric syndrome, keratoconjunctivitis, hepatitis with coagulopathy, leukocytoclastic vasculitis, and neonatal as well as adult cases of encephalitis and sepsis, interstitial pneumonitis, hemophagocytic syndromes (in children with cancer), sudden deafness, encephalitis, optic neuritis, uveitis, and septic shock. Echoviruses, and enteroviruses in general, are also a common cause of nonspecific exanthems.

Echovirus 1 (EV1) is an oncolytic virus that selectively targets and destroys malignant prostate and ovarian cancer cells in vivo and is being studied as a potential adjunctive therapy for the control of the peritoneal dissemination of gastric cancer.

As with other enterovirus infections, diagnosis is best established by correlation of clinical, epidemiologic, and laboratory evidence. Cytopathic effects are produced in tissue culture after recovery of virus from throat washings, blood, or cerebrospinal fluid. An enterovirus PCR of the cerebrospinal fluid can assist in the diagnosis and is associated with a shorter duration of hospitalization in febrile neonates. Fourfold or greater rises in antibody titer signify systemic infection.

Treatment is usually symptomatic, and the prognosis is excellent, though there are reports of mild paralysis after CNS infection. Pleconaril, investigational, appears to be of excellent, though there are reports of mild paralysis after recovery of virus from throat washings, blood, or cerebrospinal fluid. An enterovirus PCR of the cerebrospinal fluid can assist in the diagnosis and is associated with a shorter duration of hospitalization in febrile neonates. Fourfold or greater rises in antibody titer signify systemic infection.

Treatment is usually symptomatic, and the prognosis is excellent, though there are reports of mild paralysis after CNS infection. Pleconaril, investigational, appears to be of excellent, though there are reports of mild paralysis after recovery of virus from throat washings, blood, or cerebrospinal fluid. An enterovirus PCR of the cerebrospinal fluid can assist in the diagnosis and is associated with a shorter duration of hospitalization in febrile neonates. Fourfold or greater rises in antibody titer signify systemic infection.

Several distinct clinical syndromes are being described in association with enteroviruses. Enterovirus 70 (HEV-70), a ubiquitous agent first identified in 1969 and responsible for abrupt bilateral eye discharge and subconjunctival hemorrhage with occasional systemic symptoms, is most commonly associated with acute hemorrhagic conjunctivitis. Enterovirus infection of the pancreas can trigger cell-mediated autoimmune destruction of beta-cells resulting in diabetes. Enterovirus myocarditis can be a serious infection in neonates, complicated by cardiac dysfunction and arrhythmias. Enterovirus 71 (HEV-71) almost always occurs in the Asia-Pacific region and is associated with hand, foot, and mouth disease (HFMD), herpangina as well as a form of epidemic encephalitis associated on occasion with pulmonary edema, and acute flaccid paralysis. An outbreak of HFMD in Fuyang China in 2008 was caused by a recombinant virus between HEV-71 and coxsackievirus A16.

Human enteroviruses are neurotropic and a potential role for these viruses in amyotrophic lateral sclerosis is the subject of some investigation.

Mortality is especially high in enterovirus 71-associated brainstem encephalitis, which is often complicated by pulmonary edema, particularly when it occurs in children younger than 5 years. A complication is autonomic nervous system dysregulation, which may develop prior to the pulmonary edema. Because of lower herd immunity, HFMD tends to infect the very young (under age 5) in nonendemic areas. Disease is usually more severe and sequelae more common than with other enteroviruses. Some children with enterovirus-associated cardiopulmonary failure require the usage of extracorporeal life support which can improve the outcome. Recognized sequelae include central hypoventilation, dysphagia, and limb weakness.

Diagnosis of both entities is facilitated by the clinical and epidemiologic findings with the isolation of the suspect agent from conjunctival scraping for enterovirus 70 or vesicle swabs, body secretions, or cerebrospinal fluid for enterovirus 71. Serologic methods, including enzyme immunoassays and complement fixation tests, are developed. These assays show good specificity but poor sensitivity (< 80%). RT-PCR may increase the detection rate in enterovirus infections and is useful in the analysis of cerebrospinal fluid samples among patients with meningitis and of blood samples among infants with a sepsis-like illness.

Treatment of both entities remains largely symptomatic, though pleconaril (see above) may be of some use. The role of immunoglobulins is under investigation. Treatment of enterovirus 71 infections with corticosteroids or pyrazolones was associated with a worse prognosis in one study. The major complication associated with enterovirus 70 is the rare development of an acute neurologic illness with motor paralysis akin to poliomyelitis. Attention-deficit with hyperactivity occurs in about 20% with confirmed infection.

Household contacts, especially children under 6 months of age, are at particular risk for enterovirus 71 acquisition. A commercial disinfectant, Virkon S, at 1–2% application, appears to reduce infectivity titers. A stage-based supportive treatment for enterovirus 71 infections, recognizing the potential for late
onset CNS disease and cardiopulmonary failure is important. A human vaccine is needed for enterovirus 71.

**Enteroirus 72 (HEV-2)** is another term for hepatitis A virus (see Chapter 16). Enteroirus EV-104A is related to rhinoviruses and associated with respiratory illness in reports from Italy and Switzerland.

**Enteroirus 68 (HEV-68)** is a unique enterovirus that shares epidemiologic characteristics with human rhinovirus and is typically associated with respiratory illness. Several clusters are reported from the Philippines, Japan, Netherlands and the United States. The agent is implicated in a recent, fatal case of meningomyeloencephalitis.

**4. Human Parechovirus Infection (HPeV)**

HPeV is a member of the Picornaviridae family. The pathogen mainly affects small children although disease can also occur in older adults. Cases are spread worldwide. There were 16 genotypes recognized worldwide by 2011. Clinical presentation is mainly driven by gastrointestinal and respiratory illness, although otitis, neonatal sepsis, flaccid paralysis, aseptic meningitis, and encephalitis are described in the literature.

The added screening with a human parechovirus-specific PCR provides a significant increase in determining the viral cause of neonatal sepsis or CNS symptoms in children younger than 5 years. Human parechoviruses are one of the leading causes of viral sepsis and meningitis in young children. HPeV1 is the most prevalent genotype found among stool and nasopharyngeal samples in children (under 2 years old), whereas HPeV6 affects older individuals (>20 years old). HPeV3 is responsible for encephalitis, neonatal sepsis, and was recently reported in association with necrotizing enterocolitis and hepatitis. It is the most prevalent picornavirus type found in cerebrospinal fluid samples of CNS-related infections in very young children. Respiratory and gastrointestinal illnesses are seen with types HPeV4–HPeV6. Neonatal deaths are reported with HPeV3 and HPeV6. Treatment is largely supportive and rapid identification of the viral antigen by PCR in stools, respiratory samples, and cerebrospinal fluid may decrease use of unnecessary antibiotics and shorten hospital stay, although current PCR assays are not always sufficiently sensitive to exclude pachecoviruses. Reported complications of neonatal cerebral infections include learning disabilities, epilepsy, and cerebral palsy.

**1. Epidemic Louse-Borne Typhus**

**ESSENTIALS OF DIAGNOSIS**

- Prodrome of headache, then chills and fever.
- Severe, intractable headaches, prostration, persisting high fever.
- Macular rash appearing on the fourth to seventh days on the trunk and in the axillae, spreading to the rest of the body but sparing the face, palms, and soles.
- Diagnosis confirmed by specific antibodies using complement fixation, microagglutination, or immunofluorescence.

**General Considerations**

Epidemic louse-borne typhus is caused by *Rickettsia prowazekii*, an obligate parasite of the body louse *Pediculus humanus corporis* (Table 32–3). Transmission is favored by crowded, unsanitary living conditions, famine, war, or any circumstances that predispose to heavy infestation with lice. After biting a person infected with *R. prowazekii*, the louse becomes infected by the organism, which persists in the louse gut and is excreted in its feces. When the same louse bites an uninfected individual, the feces gain entry into the bloodstream when the person scratches the itching wound. Dry, infectious louse feces may also enter via the respiratory tract. Cases can be acquired by travel to pockets of infection (eg, central and northeastern Africa, Central and South America). In the last few years, outbreaks have been reported from Peru, Burundi, and Russia. Because of aerosol transmissibility, *R. prowazekii* is considered a possible bioterrorism agent.

*R. prowazekii* can survive in lymphoid tissues after primary infection, and years later, produce recrudescence of disease (Brill-Zinsser disease) without exposure to infected lice. This phenomenon can serve as a point source for future outbreaks.

An extrahuman reservoir of *R. prowazekii* in the United States is flying squirrels, *Glaucomys volans*. Transmission to humans can occur through their ectoparasites, usually causing atypical mild disease. A case of recrudescence (Brill-Zinsser) disease 11 years after the initial flying squirrel-associated disease was reported.

Harvala H et al. Comparison of human parechovirus and enterovirus detection frequencies in cerebrospinal fluid samples collected over a 5-year period in Edinburgh: HPeV type 3 identified as the most common picornavirus type. J Med Virol. 2011 May;83(5):889–96. [PMID: 21412796]

Clinical Findings

A. Symptoms and Signs

(Table 32–2). Prodromal malaise, cough, headache, backache, arthralgia, and chest pain begin after an incubation period of 10–14 days, followed by an abrupt onset of chills, high fever, and prostration, with flu-like symptoms progressing to delirium and stupor. The headache is severe and the fever is prolonged.

Other findings consist of conjunctivitis, mild vitritis, retinal lesions, optic neuritis, hearing loss from neuropathy of the eighth cranial nerve, flushed facies, rales at the lung bases, abdominal pain, myalgias, and often splenomegaly.

A macular rash (that may become confluent) appears first in the axillae and then over the trunk, spreading to the extremities but rarely involving the face, palms, or soles. In severely ill patients, the rash becomes hemorrhagic, and hypotension becomes marked. There may be acute kidney injury, stupor, seizures, and delirium. Improvement begins 13–16 days after onset with a rapid drop of fever and typically a spontaneous recovery.

B. Laboratory Findings

The white blood cell count is variable. Thrombocytopenia, elevated liver enzymes, proteinuria and hematuria commonly

Table 32–3. Rickettsial diseases.

¹Also serve as arthropod reservoirs by maintaining rickettsiae through transovarian transmission.
²Human infection results from inhalation of dust.
occurs. Serum obtained 5–12 days after onset of symptoms usually shows specific antibodies for \( R\) prowazekii antigens as demonstrated by complement fixation, microagglutination, or immunofluorescence. In primary rickettsial infection, early antibodies are IgM; in recrudescence (Brill disease), early antibodies are predominantly IgG. A PCR test exists, but its availability is limited. \( R\) prowazekii is differentiated into 7 genotypes.

C. Imaging
Radiographs of the chest may show patchy consolidation.

- **Differential Diagnosis**
  The prodromal symptoms and the early febrile stage lack enough specificity to permit diagnosis in nonepidemic situations. The rash is sufficiently distinctive for diagnosis, but it may be absent in up to 50% of cases or may be difficult to observe in dark-skinned persons. A variety of other acute febrile diseases should be considered, including typhoid fever, meningococcemia, and measles.

- **Complications**
  Pneumonia, thromboses, vasculitis with major vessel obstruction and gangrene, circulatory collapse, myocarditis, and uremia may occur.

- **Treatment**
  Treatment consists of either doxycycline (100 mg orally twice daily) or chloramphenicol (50–100 mg/kg/d in four divided doses, orally or intravenously) for 4–10 days. Chloramphenicol is considered less effective than doxycycline, but it is still the drug of choice in pregnancy. In epidemic conditions, a single dose of doxycycline can be effective and is less costly.

- **Prognosis**
  The prognosis depends greatly on the patient’s age and immune status. In children under age 10 years, the disease is usually mild. The mortality rate is 10% in the second and third decades but in the past reached 60% in the sixth decade. Brill-Zinsser disease (recrudescence epidemic typhus) has a more gradual onset than primary \( R\) prowazekii infection, fever and rash are of shorter duration, and the disease is milder and rarely fatal.

- **Prevention**
  Prevention consists of louse control with insecticides, particularly by applying chemicals to clothing or treating it with heat, and frequent bathing. The control of typhus in Finland during World War II is attributed to sauna use.

  A deloused and bathed typhus patient is not infectious. The disease is not transmitted from person to person. Patients are infectious for the lice during the febrile period and perhaps 2–3 days after the fever returns to normal. Infected lice pass rickettsiae in their feces within 2–6 days after the blood meal and can be infectious earlier if crushed. Rickettsiae remain viable in a dead louse for weeks.

  No vaccine is currently available for the prevention of \( R\) prowazekii infection. Past vaccines with crude antigen or inactivated \( Rickettsia\) provided partial protection but were associated with undesirable toxic reactions and difficulties in standardization. Efforts to identify candidate antigens through DNA technology are underway.

---

2. Endemic Flea-Borne Typhus (Murine Typhus)

\( Rickettsia typhi\), a ubiquitous pathogen recognized on all continents, is transmitted from rat to rat through the rat flea (Table 32–3). Serosurveys of animals show high prevalence of antibodies to \( R\) typhi in opossums, followed by dogs and cats. Humans usually acquire the infection in an urban or suburban setting when bitten by an infected flea, which releases infected feces while sucking blood. Rare human cases in the developed world follow travel, usually to Southeast Asia and the Mediterranean area. In the United States cases are mainly reported from Texas and Southern California. Seroprevalence studies show antibody rates to \( R\) typhi of 10% among the homeless in Houston and up to 22% in Marseilles, France.

Endemic typhus resembles recrudescent epidemic typhus in that it has a gradual onset, less severe symptoms, and a shorter duration of illness than epidemic typhus (7–10 days versus 14–21 days). The presentation is nonspecific, including fever, headache, and chills. Maculopapular rash occurs in around 50% of cases; it is concentrated on the trunk and fades fairly rapidly. Peripheral facial paralysis and splenic infarction are reported to occur. Severe disease with mental confusion and signs of hepatic, cardiac, renal, and pulmonary involvement may develop. Postinfectious optic neuritis is rare and may occur weeks after successful treatment. Fatalities are uncommon but occur especially in the elderly. Jaundice, bradycardia, and the absence of a headache are correlated with a delayed defervescence (in both epidemic and endemic typhus).

The most common entity in the differential diagnosis is Rocky Mountain spotted fever, usually occurring after a rural exposure and with a different rash (centrifugal versus centrifugal for epidemic or endemic typhus). Serologic confirmation may be necessary for differentiation, with complement-fixing or immunofluorescent antibodies detectable within 15 days after onset, with specific \( R\) typhi antigens. A fourfold rise in serum antibody titers between the acute and the convalescence phase is diagnostic.
3. Scrub Typhus (Tsutsugamushi Fever)

**ESSENTIALS OF DIAGNOSIS**

- Exposure to mites in endemic area of Southeast Asia, the western Pacific (including Korea), and Australia.
- Black eschar at site of the bite, with regional and generalized lymphadenopathy.
- High fever, headache, myalgia, and a short-lived macular rash.
- Frequent pneumonia, encephalitis, and cardiac failure.

**General Considerations**

Scrub typhus is caused by *Orientia tsutsugamushi*, which is principally a parasite of rodents and is transmitted by larval trombiculid mites (chiggers). The disease is endemic in Korea, China, Taiwan, Japan, Pakistan, India, Thailand, Malaysia and Queensland, Australia (Table 32–3), which form an area known as the “tsutsugamushi triangle”. Transmission is often more common at higher altitudes. The mites live on vegetation but complete their maturation cycle by biting humans who come in contact with infested vegetation. Therefore, the disease is more common in rural areas within these countries. Vertical transmission occurs, and blood transfusions may transmit the pathogen as well. Rare occupational transmission via inhalation is documented among laboratory workers.

**Clinical Findings**

A. Symptoms and Signs

After a 1- to 3-week incubation period, malaise, chills, severe headache and backache develop. At the site of the bite, a papule evolves into a flat black eschar, a finding which is usually helpful for diagnosis. The regional lymph nodes are commonly enlarged and tender, and sometimes a more generalized adenopathy occurs. Fever rises gradually and after 1 week, a macular rash appears primarily on the trunk area. This rash can be fleeting or last up to 1 week. The patient may become obtunded. Gastrointestinal symptoms including nausea, vomiting, and diarrhea occur in nearly two-thirds of patients and correspond to the presence of superficial mucosal hemorrhage, multiple erosions, or ulcers in the gastrointestinal tract. Both acalculous cholecystitis and acute abdominal attacks are reported. Severe complications, such as pneumonia, myocarditis and cardiac failure, encephalitis or meningitis, acute abdominal pain, granulomatous hepatitis, disseminated intravascular coagulation, ARDS, hemophagocytosis, or acute kidney disease may develop during the second or third week. An attack confers prolonged immunity against homologous strains and transient immunity against heterologous strains. Heterologous strains produce mild disease if infection occurs within a year after the first episode.

**B. Laboratory Findings**

Thrombocytopenia and elevation of liver enzymes, bilirubin, and creatinine are common. Serologic testing with immunofluorescence and immunoperoxidase assays or commercial dot-blot ELISA dipstick assays are convenient diagnostic aids, but a conclusive diagnosis requires documentation of a fourfold increase between acute and convalescence titers of antibodies. An indirect immunofluorescent assay is the mainstay of serologic diagnosis. PCR (from the eschar or blood) may be the most sensitive diagnostic test but remains positive even after the initiation of treatment. Culture of the organism (by mouse inoculation) from blood obtained in the first few days of illness is another diagnostic modality but requires a specialized BioSafety Level 3 laboratory. Filter paper immunofluorescent assays are under development, and are as sensitive and specific as paired sera, and may be especially useful in field settings.

**Differential Diagnosis**

Leptospirosis, typhoid, dengue, malaria, Q fever, hemorrhagic fevers, and other rickettsial infections should be considered. The headache may mimic trigeminal neuralgia. Scrub typhus is a recognized cause of obscure tropical fevers, especially in children.

**Treatment & Prognosis**

Without treatment, fever subsides spontaneously after 2 weeks, but the mortality rate may be 10–30%. Empiric treatment for 3 days with doxycycline, 100 mg orally twice daily, or with minocycline, 100 mg intravenously twice daily, or for 7 days with chloramphenicol, 25 mg/kg/d orally or intravenously in four divided doses, eliminates most deaths and relapses. Chloramphenicol- and tetracycline-resistant strains have been reported from Southeast Asia, where azithromycin or roxythromycin may become the drug of
choice for children, pregnant women, and patients with refractory disease. Rifampin reduces the duration of fever by 1 day when used with doxycycline.

Poor prognostic factors include requiring care in an ICU, high APACHE-II scores, age over 60 years, absence of an eschar (making the diagnosis difficult) and laboratory findings such as leukocytoysis or hypoalbuminemia. HIV infection does not appear to influence the severity of scrub typhus.

**Prevention**
Repeated application of long-acting miticides can make endemic areas safe. Insect repellents on clothing and skin as well as protective clothing are effective preventive measures. For short exposure, chemoprophylaxis with doxycycline (200 mg weekly) can prevent the disease but permits infection. No effective vaccines are available.

**Clinical Findings**

**A. Symptoms and Signs**
RMSF can cause severe multiorgan dysfunction and fatality rates of up to 73% if left untreated, making it the most serious rickettsial disease. Two to 14 days (mean, 7 days) after the bite of an infectious tick, symptoms begin with the abrupt onset of high fevers, chills, headache, nausea and vomiting, myalgias, restlessness, insomnia, and irritability.

The characteristic rash (faint macules that progress to maculopapules and then petechiae) appears between days 2 and 6 of fever. It initially involves the wrists and ankles, spreading centrally to the arms, legs, and trunk over the next 2–3 days. Involvement of the palms and soles is characteristic. Facial flushing, conjunctival injection, and hard palatal lesions (Figure 32–6) may occur. In about 10% of cases, however, no rash or only a minimal rash is seen. Cough and pneumonitis may develop and delirium, lethargy, seizures, stupor, and coma may also appear in more severe cases. Splenomegaly, hepatomegaly, jaundice, myocarditis (which may mimic an acute coronary syndrome), adrenal hemorrhage, or uremia are occasionally present.

**Figure 32–6.** Hard palate lesion caused by Rocky Mountain spotted fever. (Public Health Image Library, CDC.)

Several hours of contact between the tick and the human host are required for transmission. The brown dog tick, *Rhipicephalus sanguineus*, is a vector in eastern Arizona. Other hard ticks transmit the organism in the southern United States and in Central and South America and are responsible for transmitting it among rodents, dogs, porcupines, and other animals. There are 25 genotypes of *Rickettsia* in four different groups, and potential genomic-clinical correlations are underway.

In the United States, the estimated annual incidence of RMSF is increasing to as high as seven cases per million persons (primarily occurring from April through September), with a higher incidence among children and men. Better diagnostic capacity and improved surveillance are thought responsible for the changing epidemiology.

**General Considerations**
Despite its name, most cases of Rocky Mountain spotted fever (RMSF) occur outside the Rocky Mountain area. Passive surveillance data from 2002 to 2007 reported cases from 46 states and the District of Columbia. More than half (64%) of these cases were from only five states: North Carolina, Tennessee, Oklahoma, Missouri, and Arkansas. RMSF is endemic in Central and Southern America, with well-documented cases in Mexico, Costa Rica, Panama, Colombia, Brazil, and Argentina. The causative agent, *Rickettsia*, is transmitted to humans by the bite of ticks, including the Rocky Mountain wood tick, *D. andersoni*, in the western United States, and the American dog tick, *Dermacentor variabilis*, in the eastern United States.

**ESSENTIALS OF DIAGNOSIS**

- Exposure to tick bite in an endemic area.
- An influenza-like prodrome followed by chills, fever, severe headache, and myalgias; occasionally, delirium and coma.
- Red macular rash appears between the second and sixth days of fever, first on the wrists and ankles and then spreading centrally; it may become petechial.
- Serial serologic examinations by indirect fluorescent antibody confirm the diagnosis retrospectively.

**SPOTTED FEVERS**

1. Rocky Mountain Spotted Fever

**Figure 32–6.** Hard palate lesion caused by Rocky Mountain spotted fever. (Public Health Image Library, CDC.)
ARDS and necrotizing vasculitis, when present, are of greatest concern.

B. Laboratory Findings

Thrombocytopenia, hyponatremia, elevated aminotransferases, and hyperbilirubinemia are common. Cerebrospinal fluid may show hypoglycorrhachia and mild pleocytosis. Disseminated intravascular coagulation is observed in severe cases. Diagnosis during the acute phase of the illness can be made by immunohistologic (including PCR) demonstration of *Rickettsia* in skin biopsy specimens (or cutaneous swabs of eschars or skin lesions), but this must be performed as soon as skin lesions become apparent and before antibiotics are started to achieve maximum sensitivity. Isolation of the organism using the shell-vial technique is available in some laboratories but is hazardous.

Serologic studies confirm the diagnosis, but most patients do not mount an antibody response until the second week of illness. The indirect fluorescent antibody test is most commonly used. No commercial PCR technique is validated for serologic use.

▶ Differential Diagnosis

The diagnosis is challenging because early symptoms resemble those of many other infections. The classic triad of fever, rash, and tick bite is rarely recognized, with up to 40% of patients not recalling a tick bite. Moreover, the rash may be confused with that of measles, typhoid, and ehrlichiosis, or—most importantly—meningococcemia. Blood cultures and examination of cerebrospinal fluid establish the latter. Some spotted fever rickettsioses may also mimic RMSF.

▶ Treatment & Prognosis

Treatment with doxycycline at similar doses and duration as for epidemic typhus (see above) is recommended. Similarly, chloramphenicol is the preferred alternative during pregnancy. Patients usually defervesce within 48–72 hours and therapy should be maintained for at least 3 days after defervescence occurs. Mild cases in low-risk individuals may be observed without treatment.

The reported mortality rate in the United States is about 3–5%, but it can be as high as 70% in the untreated elderly. Infection in very young children, the presence of atypical clinical features (absence of headache, no history of tick attachment, gastrointestinal symptoms) and underlying chronic diseases, as well as a delay in initiation of appropriate antibiotic therapy are also associated with increased mortality. The usual cause of death is pneumonitis with respiratory or cardiac failure. A fulminating form of RMSF can be seen in patients with glucose-6-phosphate dehydrogenase deficiency. Sequelae, more common than formerly recognized, may include seizures, encephalopathy, peripheral neuropathy, paraparesis, bowel and bladder incontinence, cerebellar and vestibular dysfunction, hearing loss, and motor deficits. These neurologic complications are more common in those patients who require hospitalization for more than 2 weeks.

### 2. Rickettsialpox

Rickettsialpox is an acute, self-limiting, febrile illness caused by *Rickettsia akari*, a parasite of mice, transmitted by the mite *Liponyssoides sanguineus* (Table 32–3). Infections are reported globally. Seroprevalence studies done on injection drug users in inner Baltimore showed antibody positivity as high as 16%. Crowded conditions and mouse-infested housing allow transmission of the pathogen to humans. The primary lesion is a painless red papule that vesiculates and forms a black eschar followed by an incubation period of 7–12 days. Onset of symptoms is sudden, with chills, fever, headache, photophobia, and disseminated aches and pains. Two to 4 days later, a widespread papular eruption appears. The rash becomes vesicular and forms crusts that are shed in about 10 days. Early lesions may resemble those of chickenpox (typically vesicular versus papulovesicular in rickettsialpox). Pathologic findings include dermal edema, subepidermal vesicles, and at times a lymphocytic vasculitis.

Transient leukopenia and thrombocytopenia and acute hepatitis can occur. A fourfold rise in serum antibody titers to rickettsial antigen, detected by complement fixation or indirect fluorescent assays, is diagnostic. Conjugated anti-rickettsial globulin can identify antigen in punch biopsies of skin lesions. PCR detection of rickettsial DNA in fresh tissue also appears of value. *R akari* can reportedly also be isolated from eschar biopsy specimens. Treatment consists of oral doxycycline (200 mg/d) for 7 days. The disease is usually mild and self-limited without treatment, but occasionally severe symptoms may require hospitalization. Control requires the elimination of mice from human habitations and insecticide applications.

3. Tick Typhus (Rickettsial Fever)

The term “tick typhus” denotes a variety of spotted rickettsial fevers, often named by their geographic location (eg, Mediterranean spotted fever, Queensland tick typhus, Oriental spotted fever, African tick bite fever, Siberian tick typhus, North Asian tick typhus), or by morphology (eg, boutonneuse fever). These illnesses are transmitted by tick vectors of the rickettsial organisms R australis, R conorii, R japonica, R massiliae, R parkeri, and R africae (Table 32–3). Dogs and wild animals, usually rodents and even reptiles, may serve as reservoirs. Travel is a risk factor for disease, particularly among elderly ecotourists. In a series of 280 international travelers with rickettsial disease, the most common cause was spotted fever rickettsiosis (231 cases, 82.5% of the total) followed by scrub typhus (16, 5.7%). The pathogens usually produce an eschar or black spot (tâche noire) at the site of the tick bite that may be useful in diagnosis, though spotless boutonneuse fever occurs. Symptoms include fever, headache, myalgias, and rash. Rarely, papulovesicular lesions may resemble rickettsialpox. Endothelial injury produces perivascular edema and dermal necrosis. Regional adenopathy, disseminated lesions, kidney disease, splenic rupture, and focal hepatic necrosis may occur. Neurologic manifestations, including encephalitis, internuclear ophthalmoplegia, coronary involvement, and the hemophagocytic syndrome, are rare. Diabetes, dehydration, and uremia were associated with mortality in one series.

The diagnosis is clinical, with serologic or PCR used for confirmation, and treatment should be started upon clinical suspicion since delayed therapy is the usual cause of increased morbidity. Oral treatment with doxycycline (200 mg/d), chloramphenicol (50–75 mg/kg/d in four divided doses), or ciprofloxacin (500 mg twice daily) for 7–10 days is indicated. Ciprofloxacin is associated with a poor outcome and ciprofloxacin (500 mg twice daily) for 7–10 days is indicated. The combination of erythromycin and rifampin is effective and safe in pregnancy. In one reported case, R africae infection was successfully treated with pristinamycin, a streptogramin marketed in Europe. Prevention entails protective clothing, repellents, and inspection for and removal of ticks.

Formerly classified as an endemic or murine typhus, the cat-flea typhus, caused by Rickettsia felis is now more properly classified as a spotted fever. The causative agent has been linked to the cat flea and opossum exposure. Most cases in the United States (southern Texas and California, and possibly Hawaii) occur in the spring and summer. Treatment is the same as for other rickettsial fevers.

A rickettsial infection recognized as a cause of eschar-associated illness was recognized in northern California and is referred to as the spotted fever group rickettsia 364D.

OTHER RICKETTSIAL & RICKETTSIAL-LIKE DISEASES

1. Ehrlichiosis & Anaplasmosis

**ESSENTIALS OF DIAGNOSIS**

- Infection of monocyte or granulocyte by tick-borne gram-negative bacteria.
- Nine-day incubation period, with variable clinical illness, ranging from asymptomatic to persistent or life-threatening.
- Common symptoms are malaise, nausea, fever, and headaches.
- US cases are largely in elderly white men in the summer.
- Excellent response to therapy with tetracyclines.

**General Considerations**

Ehrlichiae and anaplasmas are small tick-borne gram-negative obligate intracellular bacteria that infect monocytes or granulocytes. Human monocytic ehrlichiosis is caused by *Ehrlichia chaffeensis* (Table 32–3). Human granulocytic anaplasmosis is caused by *Anaplasma phagocytophilum*. *Ehrlichia ewingii* (infesting primarily dogs) can rarely cause human granulocytic ehrlichiosis similar to human granulocytic anaplasmosis. A third *Ehrlichia* species that infects humans appears to be related to *Ehrlichia muris*. An *Ehrlichia*-like organism, *Neorickettsia sennetsu*, is the etiologic agent of sennetsu fever, which is confined to western Japan.

Human monocytic ehrlichiosis is seen primarily in the South Central states (especially Arkansas, Missouri, and Oklahoma) of the United States, although cases are also recognized in Israel, Japan, Mexico, South America, and Europe. Human granulocytic anaplasmosis is more frequent in the upper Midwestern United States; but infections in Europe and China are also well documented. Human infection with *E. ewingii* is limited to Missouri, Oklahoma, and Tennessee and occurs mainly among the immunocompromised. In North America, the major vectors for these pathogens are the Lone Star tick (*Amblyomma americanum* for *E. chaffeensis* and *E. ewingii*), the western black-legged tick (*Ixodes pacificus*, for *E. chaffeensis*), and *Ixodes scapularis* (the same vector for Lyme disease) and babesiosis for *A. phagocytophilum*. Reported incidences of both human monocytic and granulocytic ehrlichiosis are increasing and both are now at about 5 per million, respectively, with higher rates in the summer among whites and among men.

The principal reservoirs for human monocytic ehrlichiosis and human granulocytic anaplasmosis are the...
Clinical disease of human monocytic ehrlichiosis ranges from mild to life threatening. Typically, after about a 9-day incubation period and a prodrome consisting of malaise, rigors, and nausea, worsening fever and headache develop. A pleomorphic rash may occur. Presentation in immunosuppressed patients (including transplant patients) and the elderly tends to be more severe. Serious sequelae include acute respiratory failure and ARDS, encephalopathy, and acute kidney disease, which may mimic thrombotic thrombocytopenic purpura.

The symptoms of human granulocytic ehrlichiosis and *E. ewingii* infection are similar to those seen with human monocytic ehrlichiosis. Rash, however, is infrequent in human granulocytic ehrlichiosis and should prompt the consideration of other infections (eg, Lyme disease). Persistent fever and malaise are reported to occur for 2 or more years. Coinfection with Lyme disease or babesiosis may occur.

**B. Laboratory Findings**

Diagnosis can be made by the history of tick exposure followed by a characteristic clinical presentation. Leukopenia, absolute lymphopenia, thrombocytopenia, and transaminases occur often. Thrombocytopenia occurs more often than leukopenia in human granulocytic ehrlichiosis. Examination of peripheral blood with Giemsa stain may reveal characteristic intraleukocytic vacuoles (*morulae*). An indirect fluorescent antibody assay is available through the CDC and requires acute and convalescent sera. A PCR assay, if available, is a rapid diagnostic tool, especially for early disease.

**Treatment & Prevention**

Treatment for all forms of ehrlichiosis is with doxycycline, 100 mg twice daily (orally or intravenously) for at least 10 days or until 3 days of defervescence. Rifampin is an alternative in pregnant women and children. Treatment should not be withheld while awaiting confirmatory serology when suspicion is high. Lack of clinical improvement and defervescence 48 hours after doxycycline initiation suggests an alternate diagnosis. Tick control is the essence of prevention.

Pneumonia and granulomatous hepatitis are the predominant manifestation in the acute form, whereas other less common manifestations include skin rashes (maculopapular or purpuric), fever of unknown origin, myocarditis, pericarditis, aseptic meningitis, encephalitis, hemolytic anemia, orchitis, acute kidney disease, spondylodiscitis, tenosynovitis, and regional (mediastinal) or diffuse lymphadenopathies. Cases of Q fever mimicking autoimmune and systemic inflammatory disease are reported. The most common presentation of chronic Q fever is culture-negative endocarditis, which occurs in <1% of infected individuals. It is found mainly in the setting of preexisting valve disease. Vascular infections, particularly of the aorta (causing mycotic aneurysms), are the second most common form of Q fever and are associated with a high mortality (25%). Q fever chronic fatigue syndrome is thought by some experts to involve bacteremic shedding from bone marrow reservoirs and to be immunogenetically determined.

Reactivation of Q fever in pregnant women may cause spontaneous abortions, intrauterine growth retardation, intrauterine fetal death, premature delivery, and oligamnios.

B. Laboratory Findings

Laboratory examination during the acute phase may show elevated liver function tests and occasional leukocytosis. Patients with acute Q fever usually produce antibodies to C. burnetii phase II antigen. A fourfold rise between acute and convalescent sera by indirect immunofluorescence is diagnostic. Realtime PCR for C burnetii DNA is helpful only in early diagnosis of Q fever with C. burnetii DNA becoming undetectable in serum as serologic responses develop.

While chronic Q fever can be diagnosed on the basis of serologic tests done at 3- and 6-month intervals (with an IgG titer against phase I antigen of 1:1600 or greater), it is now recommended that clinical criteria be used for diagnosis of chronic disease. Diagnosis may be made at the time of valve replacement with PCR of tissue samples. C. burnetii may also be isolated from affected valves using the shell-vial technique. The organism is highly transmissible to laboratory workers and culture techniques require a biosafety level 3 setting.

C. Imaging

Radiographs of the chest show patchy pulmonary infiltrates, often more prominent than the physical signs suggest.

Differential Diagnosis

Viral, mycoplasmal, and bacterial pneumonias, viral hepatitis, brucellosis, Legionnaire disease, Kawasaki disease, tuberculosis, psittacosis, and other animal-borne diseases must be considered. Q fever should be considered in cases of unexplained fevers with negative blood cultures in association with embolic or cardiac disease.

Treatment & Prognosis

For acute infection, treatment with doxycycline (100 mg orally twice daily) for 14 days or at least 3 full days after defervescence is recommended. Even in untreated patients, the mortality rate is usually low, except when endocarditis develops.

For chronic infection, there is no agreement on the type and duration of antimicrobial therapy. Most experts recommend a combination oral therapy with doxycycline (100 mg twice a day) plus ciprofloxacin (typically 750 mg twice a day) or rifampin (300 mg twice a day) or hydroxychloroquine (200 mg three times a day) for approximately 2 years or more for the treatment of endocarditis. A study reported in 1999 of 35 patients with Q fever endocarditis showed favorable outcomes with oral doxycycline (100 mg twice a day) plus oral hydroxychloroquine (200 mg three times a day) for 18 months for native valves and 24 months for prosthetic valves. Serologic responses can be monitored during and after completion of therapy and treatment extended in the absence of favorable serologic response (considered a titer of 1:1600 or greater to phase I antigen). The general variability of serologic data, however, limits their usefulness and providers usually rely on clinical criteria. Patients should be monitored for at least 5 years due to risk of relapse. Heart valve replacement may be necessary in refractory disease. Given the difficulty in treating endocarditis, transsthoracic echocardiography is recommended for all patients with acute Q fever, and the same aforementioned therapy for 1 year should be offered in the presence of valvulopathy.

Because of the many and serious obstetric complications that occur among pregnant women in whom Q fever develops (listed above), a regimen of long-term trimethoprim-sulfamethoxazole (320/1600 mg orally for at least 5 weeks) should be given to all infected, pregnant women.

Prevention

Prevention is based on detection of the infection in livestock, reduction of contact with infected and, in particular, parturient animals or contaminated dust, special care when working with animal tissues, and effective pasteurization of milk. No vaccine is approved for use in the United States, although a whole-cell Q fever vaccine, with a 5-year efficacy of >95%, is available in Australia for persons with high-risk exposures.

C. burnetii is a category B bioterrorism agent. In the setting of a bioterrorist attack, postexposure prophylaxis with doxycycline (100 mg orally twice daily) for 5 days should be started 8–12 days after exposure. Pregnant women should take trimethoprim-sulfamethoxazole (160 mg/800 mg orally twice daily) for the duration of the pregnancy.

KAWASAKI DISEASE

ESSENTIALS OF DIAGNOSIS

- Fever, conjunctivitis, oral mucosal changes, rash, cervical lymphadenopathy, peripheral extremity changes.
- Elevated erythrocyte sedimentation rate and C-reactive protein levels.

General Considerations

Kawasaki disease is a worldwide multisystemic disease initially described by Tomisaku Kawasaki in 1967. It is also known as the "mucocutaneous lymph node syndrome." It occurs mainly in children between the ages of 3 months and 5 years but can occur occasionally in adults as well. Kawasaki disease occurs significantly more often in Asians or native Pacific Islanders than in whites. It is an acute, self-limiting, mucocutaneous vasculitis characterized by the infiltration of vessel walls with mononuclear cells and later by IgA secreting plasma cells that can result in the destruction of the tunica media and aneurysm formation. Several infectious agents (New Haven coronavirus, parvovirus, bocavirus, CMV, Yersinia pseudotuberculosis, meningococcus), bacterial superantigens, and genetic polymorphisms (confirmed in whole genome analysis) in components of the immune system (interleukin 10 and 18) are currently implicated in its pathogenesis.

Clinical Findings

A clinical diagnosis of “complete” Kawasaki disease requires, in the absence of other processes, explaining the current illness of fever and four of the following criteria for at least 5 days: bilateral nonexudative conjunctivitis, mucous membrane changes of at least one type (.injected pharynx, erythema, swelling and fissuring of the lips, strawberry tongue), peripheral extremity changes of at least one type (edema, desquamation, erythema of the palms and soles, induration of the hands and feet, Beau lines [transverse grooves of the nails]), a polymorphous rash, and cervical lymphadenopathy > 1.5 cm. An “incomplete” form is diagnosed when only two criteria are met. The classic syndrome is often preceded by nonspecific symptoms including irritability, vomiting, anorexia, cough, and diarrhea for up to 10 days.

Major complications include arteritis and aneurysms of the coronary vessels, occurring in about 25% of untreated patients, on occasion causing myocardial infarction. The pathogenesis of infarction is often thrombus formation, vasospasm, stenosis, or aneurysm rupture. Coronary complications are more common among patients older than 6 years or younger than 1 year of age. Noninvasive diagnosis of coronary complications can be made with magnetic resonance angiography or transthoracic echocardiography. Other factors associated with the development of coronary artery aneurysms are male sex, relentless fever (even after the administration of IVIG), high C-reactive protein, urticarial exanthesms, anemia, hypoalbuminemia, hyponatremia, and thrombocytopenia. Pericardial effusions, myocarditis, and mitral regurgitation (usually mild) are also common. Coronary artery fistulas occur in up to 5% of patients and diastolic dysfunction is also reported. Arteritis of extremity vessels, peripheral gangrene, syndrome of inappropriate secretion of antidiuretic hormone (SIADH), and the hemophagocytic syndrome are also reported. Cases of pancreatitis and bile duct stenosis due to underlying vasculitis are reported. Cerebrospinal fluid pleocytosis is found in one-third of cases and encephalitis is rarely reported. Other CNS complications include seizures, oculomotor palsies, and sensorineural hearing loss which, when sought, can be found in as many as 55% of cases. Rare case reports of atypical presentations (eg, retropharyngeal abscess) are described.

Differentiation from disseminated adenovirus infection is important and can be performed with rapid adenovirus assays.

Treatment & Prevention

Every patient with a clinical diagnosis of Kawasaki disease (complete or incomplete) should be treated. IVIG (2 g/kg over 10–12 hours) is given within the first 10 days of illness. For those presenting later, but with persistent fever, ongoing systemic inflammation, or aneurysm formation, IVIG should be offered as well. Concomitant aspirin should be started at 80–100 mg/kg/d orally (divided into four doses and not exceeding 4 g/d) until the patient is afebrile for 48 hours and then reduced to 3–5 mg/kg/d until markers of acute inflammation normalize. Aspirin therapy is continued if coronary aneurysm develops. If fevers persist beyond 36 hours after the initial IVIG infusion, a second dose of IVIG at 2 g/kg should be given if no other source of fever is found. Rare cases of aseptic meningitis are reported with IVIG, and this complication may be hard to distinguish from the occasional CNS disease associated with Kawasaki syndrome itself although the time course and the cerebrospinal fluid differential (more polymorphonuclear with IVIG, more lymphocytic with Kawasaki syndrome) may help differentiate the two. Methylprednisolone (30 mg/kg/d intravenously if possible for a maximum of 3 days) followed by tapering dose of corticosteroids should follow if the disease persists after the second IVIG administration. Routine childhood vaccinations should be given and live vaccines (eg, MMR) should be delayed for at least 9 months only if IVIG was administered (because IVIG can block the immune response to live vaccines). If vaccine preventable disease endemicity requires urgent vaccination, it is prudent to revaccinate 11 months after the IVIG and first vaccination were given.

Further options for refractory cases include TNF blockers (infliximab or etanercept), cyclophosphamide, methotrexate, and plasmapheresis. Abciximab therapy may be associated with coronary vessel remodeling in large coronary artery aneurysms. An echocardiogram is essential in the acute phase of illness and 6–8 weeks after onset. Anticoagulation with warfarin or low-molecular-weight heparin (the latter is preferable for children where dosage...
adjustments are difficult using warfarin) is indicated along with aspirin, 81 mg orally daily, in patients with aneurysms > 8 mm in diameter. If myocardial infarction occurs, therapy with thrombolitics, percutaneous coronary intervention, coronary artery bypass grafts, and even cardiac transplantation should be considered. Manifestation of coronary artery aneurysms can occur as late as in the third or fourth decade of life. Data are equivocal on the development of accelerated atherosclerosis among those with a history of Kawasaki disease.

While secondary prevention of complications entails the modalities described above, primary prevention is difficult in the absence of a clear explanation for the disease.

**Prognosis**

Cases that develop recurrent disease tend to more often show cardiac complications. Patients with a parental history of Kawasaki disease show more recurrent disease and more cardiac complications. The long-term prognosis for adults with a history of Kawasaki disease but without coronary artery aneurysms is excellent. A heart-healthy lifestyle, however, is essential. The prognosis of patients with a history of cardiac complications requires regular follow-up with risk stratification based on published guidelines and under cardiologic supervision. Children with Kawasaki disease appear to have an increased risk for subsequent allergic diseases.

**When to Refer**

All cases of Kawasaki disease merit referral to specialists.

Infections caused by Gram-Positive Bacteria

**Streptococcal Infections**

1. **Pharyngitis**

**Essentials of Diagnosis**

- Abrupt onset of sore throat, fever, malaise, nausea, and headache.
- Throat red and edematous, with or without exudate; cervical nodes tender.
- Diagnosis confirmed by culture of throat.

**General Considerations**

Group A β-hemolytic streptococci (Streptococcus pyogenes) are the most common bacterial cause of pharyngitis. Transmission occurs by droplets of infected secretions. Group A streptococci producing erythrogenic toxin may cause scarlet fever in susceptible persons.

**Clinical Findings**

**A. Symptoms and Signs**

“Strep throat” is characterized by a sudden onset of fever, sore throat, pain on swallowing, tender cervical adenopathy, malaise, and nausea. The pharynx, soft palate, and tonsils are red and edematous. There may be a purulent exudate. The Centor clinical criteria for the diagnosis of streptococcal pharyngitis are temperature > 38 °C, tender anterior cervical adenopathy, lack of a cough, and pharyngotonsillar exudate.

The rash of scarlet fever is diffusely erythematous, resembling a sunburn, with superimposed fine red papules, and is most intense in the groin and axillae. It blanches on pressure, may become petechial, and fades in 2–5 days, leaving a fine desquamation. The face is flushed, with circumoral pallor, and the tongue is coated with enlarged red papillae (strawberry tongue).

**B. Laboratory Findings**

Leukocytosis with neutrophil predominance is common. Throat culture onto a single blood agar plate has a sensitivity of 80–90%. Rapid diagnostic tests based on detection of streptococcal antigen are slightly less sensitive than culture. Clinical criteria, such as the Centor criteria, are useful for identifying patients in whom a rapid antigen test or throat culture is indicated. Patients who meet two or more of these criteria merit further testing. When three of the four are present, laboratory sensitivity of rapid antigen testing exceeds 90%. When only one criterion is present, streptococcal pharyngitis is unlikely. In high-prevalence settings or if clinical suspicion for streptococcal pharyngitis is high, a negative antigen test or culture should be confirmed by a follow-up culture.

**Complications**

Suppurative complications include sinusitis, otitis media, mastoiditis, peritonsillar abscess, and suppuration of cervical lymph nodes.

Nonsuppurative complications are rheumatic fever and glomerulonephritis. Rheumatic fever may follow recurrent episodes of pharyngitis beginning 1–4 weeks after the onset of symptoms. Glomerulonephritis follows a single infection with a nephritogenic strain of streptococcus group A (eg, types 4, 12, 2, 49, and 60), more commonly on the skin than in the throat, and begins 1–3 weeks after the onset of the infection.

**Differential Diagnosis**

Streptococcal sore throat resembles (and cannot be reliably distinguished clinically from) pharyngitis caused by Fusobacterium necrophorum, adeno- viruses, Epstein-Barr virus, primary HIV, Arcanobacterium haemolyticum (which also may cause a rash), and other agents. Pharyngitis and lymphadenopathy are common findings in primary HIV infection. Generalized lymphadenopathy, splenomegaly, atypical lymphocytosis, and a positive serologic test distinguish mononucleosis from streptococcal pharyngitis. Diphtheria is characterized by a pseudomembrane; candidiasis shows white patches of exudate and less erythema;
and necrotizing ulcerative gingivostomatitis (Vincent fusospirochet al gingivitis or stomatitis) presents with shallow ulcers in the mouth. Retropharyngeal abscess or bacterial epiglottitis should be considered when odynophagia and difficulty in handling secretions are present and when the severity of symptoms is disproportionate to findings on examination of the pharynx. *F. necrophorum* causes pharyngitis at a similar rate as group A β-hemolytic streptococci in adolescents and young adults. *F. necrophorum* pharyngitis is associated with Lemierre syndrome, suppurative thrombophlebitis of the internal jugular vein, bacteremia, and metastatic infections. Early recognition and treatment of this disease is important.

**Treatment**

Antimicrobial therapy has a modest effect on resolution of symptoms and primarily is administered for prevention of complications. Antibiotic therapy can be safely delayed until the diagnosis is established on the basis of a positive antigen test or culture. Empiric therapy usually is not a cost-effective approach to the management of most adults with pharyngitis because the prevalence of streptococcal pharyngitis is likely to be no more than 10–20% in typical clinical settings. The positive predictive value of clinical criteria is low. Since macrolides are not reliable against *F. necrophorum* infection, adolescents or young adults with pharyngitis, which is not confirmed to be due to group A β-hemolytic streptococci, should be given penicillin or amoxicillin preferentially at the doses listed below. If the pharyngitis does not resolve quickly, symptoms worsen, or unilateral neck swelling develops, clinicians should consider suppurative complications such as peritonsillar abscess and the Lemierre syndrome.

A. Benzathine Penicillin G

Benzathine penicillin G, 1.2 million units intramuscularly as a single dose, is optimal therapy.

B. Penicillin VK

Penicillin VK, 500 mg orally four times a day (or amoxicillin, 750 mg orally twice daily) for 10 days, is effective, but compliance may be poor after the patient becomes asymptomatic in 2–4 days.

C. Cephalosporins

Cefdinir, 300 mg orally twice daily for 5–10 days or 600 mg orally once daily for 10 days, and cefpodoxime, 100 mg orally twice daily for 5–10 days, are both approved by the US Food and Drug Administration (FDA) for the treatment of streptococcal pharyngitis but should be reserved for penicillin-allergic patients able to tolerate cephalosporins.

D. Macrolides

Erythromycin, 500 mg orally four times a day, or azithromycin, 300 mg orally once daily for 3 days, is an alternative for the penicillin-allergic patient. Macrolides are less effective than penicillins and are considered second-line agents.

Macrolide-resistant strains almost always are susceptible to clindamycin, a suitable alternative to penicillins; a 10-day course of 300 mg orally twice daily is effective.

**Prevention of Recurrent Rheumatic Fever**

Effectively controlling rheumatic fever depends on identification and treatment of primary streptococcal infection and secondary prevention of recurrences. Patients who have had rheumatic fever should be treated with a continuous course of antimicrobial prophylaxis for at least 5 years. Effective regimens are erythromycin, 250 mg orally twice daily, or penicillin G, 500 mg orally daily.

---

2. Streptococcal Skin Infections

Group A β-hemolytic streptococci are not normal skin flora. Streptococcal skin infections result from colonization of normal skin by contact with other infected individuals or by preceding streptococcal respiratory infection.

**Clinical Findings**

A. Symptoms and Signs

Impetigo is a focal, vesicular, pustular lesion with a thick, amber-colored crust with a “stuck-on” appearance (see Chapter 6).

Erysipelas is a painful superficial cellulitis that frequently involves the face. It is well demarcated from the surrounding normal skin. It affects skin with impaired lymphatic drainage, such as edematous lower extremities or wounds.

B. Laboratory Findings

Cultures obtained from a wound or pustule are likely to grow group A streptococci. Blood cultures are occasionally positive.

**Treatment**

Parenteral antibiotics are indicated for patients with facial erysipelas or evidence of systemic infection. Penicillin, 2 million units intravenously every 4 hours, is the drug of choice. However, staphylococci infections may at times be difficult to differentiate from streptococcal infections. In practice, initial therapy for patients with risk factors for *Staphylococcus aureus* (eg, injection drug use, diabetes, wound infection) should cover this organism. Nafcillin, 1–2 g every 4–6 hours intravenously, and cefazolin, 1 g intravenously or intramuscularly every 8 hours, are reasonable choices. In the patient at risk for methicillin-resistant...
Purulent (abscess, furuncle, carbuncle, cellulitis with purulence) | Staphylococcus aureus | Incision and drainage is the primary treatment. Consider the addition of antibiotics in select situations.1

**Oral antibiotic regimens**
- Cephalexin 500 mg four times daily or dicloxacillin 500 mg four times daily
- Clindamycin 300–450 mg three or four times daily2 or one double-strength tablet of trimethoprim-sulfamethoxazole twice daily2 or doxycycline 100 mg twice daily2

**Intravenous antibiotic regimens**
- Cefazolin 1 g three times daily or nafcillin 1–2 g four to six times daily
- Vancomycin 1 g twice daily2 or daptomycin 4 mg/kg once daily2

Nonpurulent (cellulitis, erysipelas) | β-hemolytic streptococci (S aureus less likely) | Oral antibiotic regimens
- Cephalexin 500 mg four times daily or dicloxacillin 500 mg four times daily
- Clindamycin 300–450 mg three or four times daily2 or amoxicillin 875 mg twice daily plus one double-strength tablet of trimethoprim-sulfamethoxazole twice daily2

**Intravenous antibiotic regimens**
- Cefazolin 1 g three times daily or nafcillin 1–2 g four to six times daily
- Vancomycin 1 g twice daily2 or daptomycin 4 mg/kg once daily2

1Antibiotic therapy should be given in addition to incision and drainage for purulent SSTI if the patient has any of the following: severe or extensive disease, signs and symptoms of systemic illness, purulent cellulitis/wound infection, comorbidities and extremes of age, abscess in area difficult to drain or face/hand, associated septic phlebitis, or lack of response to incision and drainage alone.

2Regimens with activity against methicillin-resistant S aureus (can also be given by mouth); tigecycline, 50 mg twice daily; telavancin, at 10 mg/kg once daily; and cefotaroline, 600 mg twice daily.

S aureus infection or with a serious penicillin allergy (ie, anaphylaxis), vancomycin, 1 g intravenously every 12 hours, or daptomycin 4 mg/kg intravenously daily, should be used (Table 33–1).

Patients who do not require parenteral therapy may be treated with amoxicillin, 875 mg twice daily for 7–10 days. A first-generation oral cephalosporin, eg, cephalaxin, 500 mg four times daily, or clindamycin, 300 mg orally three times daily, is an alternative to amoxicillin.

3. Other Group A Streptococcal Infections

Arthritis, pneumonia, empyema, endocarditis, and necrotizing fasciitis are relatively uncommon infections that may be caused by group A streptococci. Toxic shock-like syndrome also occurs.

**Arthritis** generally occurs in association with cellulitis. In addition to intravenous therapy with penicillin G, 2 million units every 4 hours (or cefazolin or vancomycin in doses recommended above for penicillin-allergic patients), frequent percutaneous needle aspiration should be performed to remove joint effusions. Open surgical drainage may be necessary in many cases.

**Pneumonia** and **empyema** often are characterized by extensive tissue destruction and an aggressive, rapidly progressive clinical course associated with significant morbidity and mortality. High-dose penicillin and chest tube drainage are indicated for treatment of empyema. Vancomycin is an acceptable substitute in penicillin-allergic patients.

Group A streptococci can cause **endocarditis**. Endocarditis should be treated with 4 million units of penicillin G intravenously every 4 hours for 4–6 weeks.

Vancomycin, 1 g intravenously every 12 hours, is recommended for persons allergic to penicillin.

**Necrotizing fasciitis** is a rapidly spreading infection involving the fascia of deep muscle. The clinical findings at presentation may be those of severe cellulitis, but the presence of systemic toxicity and severe pain, which may be followed by anesthesia of the involved area due to destruction of nerves as infection advances through the fascial planes, is a clue to the diagnosis. Surgical exploration is mandatory when the diagnosis is suspected. Early and extensive debridement is essential for survival.

Any streptococcal infection—and necrotizing fasciitis in particular—can be associated with streptococcal toxic shock syndrome, typified by invasion of skin or soft tissues, acute respiratory distress syndrome, and kidney failure. The very young, the elderly, and those with underlying medical conditions are at particularly high risk for invasive disease. Bacteremia occurs in most cases. Skin rash and desquamation may not be present. Mortality rates can be up to 80%. The syndrome is due to elaboration of pyrogenic erythrogenic toxin (which also causes scarlet fever), a superantigen that stimulates massive release of inflammatory cytokines believed to mediate the shock. A β-lactam, such as penicillin, remains the drug of choice for treatment of serious streptococcal infections, but clindamycin, which is a potent inhibitor of toxin production, should also be administered at a dose of 600 mg every 8 hours intravenously for invasive disease, especially in the presence of shock. Intravenous immune globulin has also been recommended for streptococcal toxic shock syndrome for presumed, although unproven, therapeutic benefit from specific antibody to streptococcal exotoxins in immune
globulin preparations. Two dosage regimens have been used: 450 mg/kg once daily for 5 days or a single dose of 2 g/kg with a repeat dose at 48 hours if the patient remains unstable.

Outbreaks of invasive disease have been associated with colonization by invasive clones that can be transmitted to close contacts who, though asymptomatic, may be a reservoir for disease. Tracing contacts of patients with invasive disease is controversial.

Resistance to vancomycin, penicillin, and gentamicin is common among enterococcal isolates, especially *E faecium*; it is essential to determine antimicrobial susceptibility of isolates. Infection control measures that may be indicated to limit their spread include isolation, barrier precautions, and avoidance of overuse of vancomycin and gentamicin. Consultation with an infectious diseases specialist is strongly advised when treating infections caused by resistant strains of enterococci. Quinupristin/dalfopristin and linezolid are approved by the FDA for treatment of infections caused by vancomycin-resistant strains of enterococci.

Quinupristin/dalfopristin is not active against strains of *E faecalis* and should be used only for infections caused by *E faecium*. The dose is 7.5 mg/kg intravenously every 8–12 hours. Phlebitis and irritation at the infusion site (often requiring a central line) and an arthralgia-myalgia syndrome are relatively common side effects. Linezolid, an oxazolidinone, is active against both *E faecalis* and *E faecium*. The dose is 600 mg twice daily, and both intravenous and oral preparations are available. Its two principal side effects are thrombocytopenia and bone marrow suppression; however, peripheral neuropathy, optic neuritis, and lactic acidosis have been observed with prolonged use due to mitochondrial toxicity. Emergence of resistance has occurred during therapy with either quinupristin/dalfopristin or linezolid.

### PNEUMOCOCCAL INFECTIONS

#### 1. Pneumococcal Pneumonia

**ESSENTIALS OF DIAGNOSIS**

- Productive cough, fever, rigors, dyspnea, early pleuritic chest pain.
- Consolidating lobar pneumonia on chest radiograph.
- Gram-positive diplococci on Gram stain of sputum.

**General Considerations**

The pneumococcus is the most common cause of community-acquired pyogenic bacterial pneumonia. Alcoholism,
asthma, HIV infection, sickle cell disease, splenectomy, and hematologic disorders are predisposing factors. The mortality rate remains high in the setting of advanced age, multilobar disease, severe hypoxemia, extrapulmonary complications, and bacteremia.

### Clinical Findings

#### A. Symptoms and Signs

Presenting symptoms and signs include high fever, productive cough, occasionally hemoptysis, and pleuritic chest pain. Rigors occur within the first few hours of infection but are uncommon thereafter. Bronchial breath sounds are an early sign.

#### B. Laboratory Findings

Pneumococcal pneumonia classically is a lobar pneumonia with radiographic findings of consolidation and occasionally effusion. However, differentiating it from other pneumonias is not possible radiographically or clinically because of significant overlap in presentations. Diagnosis requires isolation of the organism in culture, although the Gram stain appearance of sputum can be suggestive. Sputum and blood cultures, positive in 60% and 25% of cases of pneumococcal pneumonia, respectively, should be obtained prior to initiation of antimicrobial therapy in patients who are admitted to the hospital. A good-quality sputum sample (>10 epithelial cells and >25 polymorphonuclear leukocytes per high-power field) shows gram-positive diplococci in 80–90% of cases. A rapid urinary antigen test for *S. pneumoniae*, with sensitivity of 70–80% and specificity >95%, can assist with early diagnosis.

#### Complications

Parapneumonic (sympathetic) effusion is common and may cause recurrence or persistence of fever. These sterile fluid accumulations need no specific therapy. Empyema occurs in 5% or less of cases and is differentiated from sympathetic effusion by the presence of organisms on Gram-stained fluid or positive pleural fluid cultures.

Pneumococcal pericarditis is a rare complication that can cause tamponade. Pneumococcal arthritis also is uncommon. Pneumococcal endocarditis usually involves the aortic valve and often occurs in association with meningitis and pneumonia (sometimes referred to as Austrian or Osler triad). Early heart failure and multiple embolic events are typical.

#### Treatment

##### A. Specific Measures

Initial antimicrobial therapy for pneumonia is empiric (see Chapter 9 for specific recommendations) pending isolation and identification of the causative agent. Once the pneumonia is determined to be caused by *Streptococcus pneumoniae*, any of several antimicrobial agents may be used depending on the clinical setting, community patterns of penicillin resistance, and susceptibility of the particular isolate. Uncomplicated pneumococcal pneumonia (ie, arterial P\textsubscript{O\textsubscript{2}} > 60 mm Hg, no coexisting medical problems, and single-lobe disease without signs of extrapulmonary infection) caused by penicillin-susceptible strains of pneumococcus may be treated on an outpatient basis with amoxicillin, 750 mg orally twice daily for 7–10 days. For penicillin-allergic patients, alternatives are azithromycin, one 500-mg dose orally on the first day and 250 mg for the next 4 days; clarithromycin, 500 mg orally twice daily for 10 days; doxycycline, 100 mg orally twice daily for 10 days; levofloxacin, 750 mg orally for 5 days; or moxifloxacin, 400 mg orally for 7–14 days. Patients should be monitored for clinical response (eg, less cough, defervescence within 2–3 days) because pneumococci have become increasingly resistant to penicillin and the second-line agents.

Parenteral therapy is generally recommended for the hospitalized patient at least until there has been clinical improvement. Aqueous penicillin G, 2 million units intravenously every 4 hours, or ceftriaxone, 1 g intravenously every 24 hours, is effective for strains that are not highly penicillin-resistant (ie, strains for which the minimum inhibitory concentration [MIC] of penicillin is ≤1 mcg/mL). For serious pneumococcal allergy or infection caused by a highly penicillin-resistant strain, vancomycin, 1 g intravenously every 12 hours, is effective. Alternatively, a respiratory fluoroquinolone (eg, levofloxacin, 750 mg) can be used. The total duration of therapy is not well defined but 7–14 days is standard.

#### B. Treatment of Complications

Pleural effusions developing after initiation of antimicrobial therapy usually are sterile, and thoracentesis need not be performed if the patient is otherwise improving. Thoracentesis is indicated for an effusion present prior to initiation of therapy and in the patient who has not responded to antibiotics after 3–4 days. Chest tube drainage may be required if pneumococci are identified by culture or Gram stain, especially if aspiration of the fluid is difficult.

Echocardiography should be done if pericardial effusion is suspected. Patients with pericardial effusion who are responding to therapy and have no signs of tamponade may be monitored and treated with indomethacin, 50 mg orally three times daily, for pain. In patients with increasing effusion, unsatisfactory clinical response, or evidence of tamponade, pericardiocentesis will determine whether the pericardial space is infected. Infected fluid must be drained either percutaneously (by tube placement or needle aspiration), by placement of a pericardial window, or by pericardiectomy. Pericardiectomy eventually may be required to prevent or treat constrictive pericarditis, a common sequela of bacterial pericarditis.

Endocarditis should be treated for 4 weeks with 3–4 million units of penicillin G every 4 hours intravenously; ceftriaxone, 2 g once daily intravenously; or vancomycin, 15 mg/kg every 12 hours intravenously. Mild heart failure from endocarditis may respond to medical therapy, but moderate to severe heart failure is an indication for prosthetic valve implantation, as are systemic emboli or large friable vegetations as determined by echocardiography.
C. Penicillin-Resistant Pneumococci

Susceptibility breakpoints defining penicillin-resistant pneumococci for isolates causing pneumonia were revised in 2008. Resistance breakpoints for parenterally administered penicillin and high-dose oral amoxicillin (2 g twice daily) are as follows: susceptible, penicillin MIC ≤ 2 mcg/mL; intermediate, MIC = 4 mcg/mL; resistant, MIC ≥ 8 mcg/mL. This change reflected results from studies demonstrating equivalent cure rates when high doses of parenteral penicillin were used for treatment of pneumococcal pneumonia due to isolates with penicillin MIC ≤ 2 mcg/mL. Note, however, that these new breakpoints do not apply to orally administered penicillin, which are the same as for use of penicillin in treatment of meningitis (see below). In cases of pneumococcal pneumonia where the isolate has a penicillin MIC > 2 mcg/mL, cephalosporin cross-resistance is common, and a non-β-lactam antimicrobial, such as vancomycin, 1 g intravenously every 12 hours or a fluoroquinolone with enhanced gram-positive activity (eg, levofloxacin, 750 mg intravenously or orally once daily or moxifloxacin, 400 mg intravenously or orally once daily), is recommended. Penicillin-resistant strains of pneumococci may be resistant to macrolides, trimethoprim-sulfamethoxazole, and chloramphenicol, and susceptibility must be documented prior to their use. All blood and cerebrospinal fluid isolates should still be tested for resistance to penicillin. There has been no change to the penicillin susceptibility breakpoint for pneumococcal isolates causing meningitis, nor any change in treatment recommendations (see below).

2. Pneumococcal Meningitis

General Considerations

S pneumoniae is the most common cause of meningitis in adults. Head trauma, with cerebrospinal fluid leaks, sinusitis, and pneumonia may precede it.

Clinical Findings

A. Symptoms and Signs

The onset is rapid, with fever, headache, meningeal, and altered mentation. Pneumonia may be present. Compared with meningitis caused by the meningococcus, pneumococcal meningitis lacks a rash, and focal neurologic deficits, cranial nerve palsies, and obtundation are more prominent features.

B. Laboratory Findings

The cerebrospinal fluid typically has > 1000 white blood cells per microliter, over 60% of which are polymorphonuclear leukocytes; the glucose concentration is < 40 mg/dL, or < 50% of the simultaneous serum concentration; and the protein usually exceeds 150 mg/dL. Not all cases of meningitis will have these typical findings, and alterations in cerebrospinal fluid cell counts and chemistries may be surprisingly minimal, overlapping with those of aseptic meningitis.

Gram stain of cerebrospinal fluid shows gram-positive cocci in 80–90% of cases, and in untreated cases, blood or cerebrospinal fluid cultures are almost always positive.

Treatment

Antibiotics should be given as soon as the diagnosis is suspected. If lumbar puncture must be delayed (eg, while awaiting results of an imaging study to exclude a mass lesion), the patient should be treated empirically for presumed meningitis with intravenous ceftriaxone, 2 g, plus vancomycin, 15 mg/kg, plus dexamethasone, 0.15 mg/kg administered concomitantly after blood cultures (positive in 50% of cases) have been obtained. Once susceptibility to penicillin has been confirmed, penicillin, 24 million units intravenously daily in six divided doses, or ceftriaxone, 2 g every 12 hours intravenously, is continued for 10–14 days in documented cases.

The best therapy for penicillin-resistant strains is not known. Penicillin-resistant strains (MIC > 0.06 mcg/mL) are often cross-resistant to the third-generation cephalosporins as well as other antibiotics. Susceptibility testing is essential to proper management of this infection. If the MIC of ceftriaxone or cefotaxime is ≤ 0.5 mcg/mL, single-drug therapy with either of these cephalosporins is likely to be effective; when the MIC is ≥ 1 mcg/mL, treatment with a combination of ceftriaxone, 2 g intravenously every 12 hours, plus vancomycin, 30 mg/kg/d intravenously in two or three divided doses, is recommended. If a patient with a penicillin-resistant organism is slow to respond clinically, repeat lumbar puncture may be indicated to assess bacteriologic response.

Dexamethasone administered with antibiotic to adults has been associated with a 60% reduction in mortality and a 50% reduction in unfavorable outcomes. It is recommended that dexamethasone, 10 mg intravenously, be given immediately prior to or concomitantly with the first dose of appropriate antibiotic and continued in those with pneumococcal disease every 6 hours thereafter for a total of 4 days. Patients with pneumococcal meningitis and AIDS
who do not have access to resources may not benefit from dexamethasone. The effect of dexamethasone on outcome of meningitis caused by penicillin-resistant organisms is not known.

STAPHYLOCOCCUS AUREUS INFECTIONS

1. Skin & Soft Tissue Infections

ESSENTIALS OF DIAGNOSIS

- Localized erythema with induration and purulent drainage.
- Abscess formation.
- Folliculitis commonly observed.
- Gram stain of pus with gram-positive cocci in clusters; cultures usually positive.

General Considerations

Approximately one-quarter of people are asymptomatic nasal carriers of *S. aureus*, which is spread by direct contact. Carriage often precedes infection, which occurs as a consequence of disruption of the cutaneous barrier or impairment of host defenses. *S. aureus* tends to cause more localized skin infections than streptococci, and abscess formation is common. The prevalence of methicillin-resistant strains in community settings is increasing, and these strains have been associated with recurrent and severe skin and soft tissue infections, including necrotizing fasciitis.

Clinical Findings

A. Symptoms and Signs

*S. aureus* skin infections may begin around one or more hair follicles, causing folliculitis; may become localized to form boils (or furuncles); or may spread to adjacent skin and deeper subcutaneous tissue (ie, a carbuncle) (Figure 33–1). Deep abscesses involving muscle or fascia may occur, often in association with a deep wound or other inoculation or injection. Necrotizing fasciitis, a rare form of *S. aureus* skin and soft tissue infections, has been reported with community strains of methicillin-resistant *S. aureus*.

B. Laboratory Findings

Cultures of the wound or abscess material will almost always yield the organism. In patients with systemic signs of infection, blood cultures should be obtained because of potential endocarditis, osteomyelitis, or metastatic seeding of other sites. Patients who are bacteremic should have blood cultures taken early during therapy to exclude persistent bacteremia, an indicator of severe or complicated infection.

Treatment

Proper drainage of abscess fluid or other focal infections is the mainstay of therapy. Incision and drainage alone may be sufficient for cutaneous abscess. For uncomplicated skin infections, oral antimicrobial therapy is satisfactory. Before the emergence of community methicillin-resistant strains of *S. aureus*, an oral penicillinase-resistant penicillin or cephalosporin, such as dicloxacillin or cephalaxin, 500 mg four times a day for 7–10 days, was the drug of choice for empiric therapy. However, increasing prevalence of methicillin-resistant strains of *S. aureus* among community isolates may necessitate use of other oral agents to which the isolate is susceptible in vitro, such as clindamycin, 300 mg three times daily; doxycycline or minocycline, 100 mg twice daily; or trimethoprim-sulfamethoxazole, given in two divided doses based on 5–10 mg/kg/d of the trimethoprim component. Unfortunately, the efficacy of these agents is not well defined and not evidence based. Because of the high prevalence of macrolide resistance among *S. aureus* strains, these agents should not be used unless susceptibility is documented (see Table 33–1).

For more complicated infections with extensive cutaneous or deep tissue involvement or fever, parenteral therapy is indicated initially. A penicillinase-resistant penicillin such as nafcillin or oxacillin in a dosage of 1.5 g every 6 hours intravenously or cefazolin 1 g intravenously or intramuscularly is preferred for infections caused by methicillin-susceptible isolates. In patients with a serious allergy to β-lactam antibiotics or if the strain is methicillin-resistant, vancomycin, 1 g intravenously every 12 hours, is a drug of choice. If the local prevalence of methicillin-resistance is high (eg, 10% or more), and particularly if the patient is seriously ill, vancomycin is indicated empirically pending strain isolation and determination of susceptibility.
Linezolid is FDA-approved for treatment of skin and skin-structure infections as well as hospital-acquired pneumonia caused by methicillin-resistant strains of S aureus and clinically is as effective as vancomycin. The dose is 600 mg orally (bioavailability of 100%) or intravenously twice a day for 10–14 days. Its considerable cost makes it an unattractive choice for most routine outpatient infections, and its safety in treatment courses lasting longer than 2–3 weeks is not well characterized; nevertheless, it is the only proven effective oral alternative to parenteral vancomycin. Daptomycin, 4 mg/kg once daily (or every other day in the patient with creatinine clearance < 30 mL/min) intravenously for 7–14 days, is also an option for treatment of complicated skin and skin structure infections. Tigecycline (a glycylcycline class antimicrobial), telavancin (a lipoglycopeptide), and ceftaroline (a novel cephalosporin with activity against methicillin-resistant S aureus) are all approved by the FDA for treatment of complicated skin and skin structure infections due to methicillin-resistant strains of S aureus. The dosage of tigecycline is 100 mg intravenously once followed by 50 mg intravenously twice a day. The dose of telavancin is 10 mg/kg intravenously once daily for 7–14 days. The dosage of ceftaroline is 600 mg twice a day for 7–14 days.

2. Osteomyelitis

S aureus causes approximately 60% of all cases of osteomyelitis. Osteomyelitis may be caused by direct inoculation, eg, from an open fracture or as a result of surgery; by extension from a contiguous focus of infection or open wound; or by hematogenous spread. Long bones and vertebrae are the usual sites. Epidural abscess is a common complication of vertebral osteomyelitis and should be suspected if fever and severe back or neck pain are accompanied by radicular pain or symptoms and signs indicative of spinal cord compression (eg, incontinence, extremity weakness, pathologic reflexes).

Clinical Findings

A. Symptoms and Signs

The infection may be acute, with abrupt development of local symptoms and systemic toxicity, or indolent, with insidious onset of vague pain over the site of infection, progressing to local tenderness and constitutional symptoms (fever, malaise, anorexia, night sweats). Fever is absent in one-third or more of cases. Back pain is often the only symptom in vertebral osteomyelitis and may be associated with an epidural abscess and spinal cord compression. Draining sinus tracts occur in chronic infections or infections of foreign body implants.

B. Laboratory Findings

The diagnosis is established by isolation of S aureus from the blood, bone, or a contiguous focus of a patient with signs and symptoms of focal bone infection. Blood culture will be positive in approximately 60% of untreated cases. Bone biopsy and culture are indicated if blood cultures are sterile.

C. Imaging

Bone scan and gallium scan, each with a sensitivity of approximately 95% and a specificity of 60–70%, are useful in identifying or confirming the site of bone infection. Plain bone films early in the course of infection are often normal but will become abnormal in most cases even with effective therapy. Spinal infection (unlike malignancy) traverses the disk space to involve the contiguous vertebral body. CT is more sensitive than plain films and helps localize associated abscesses. MRI is slightly less sensitive than bone scan but has a specificity of 90%. It is indicated when epidural abscess is suspected in association with vertebral osteomyelitis.

Treatment

Prolonged therapy is required to cure staphylococcal osteomyelitis. Durations of 4–6 weeks or longer are recommended. In cases of staphylococcal osteomyelitis with associated epidural abscess and spinal cord compression, other abscesses (psoas, paraspinal) or extensive disease, surgical treatment is often indicated. Although oral regimens can be effective, intravenous therapy is preferred, particularly during the acute phase of the infection for patients with systemic toxicity. Nafcillin or oxacillin, 9–12 g/d in six divided doses, is the drug of choice for infection with methicillin-sensitive isolates. Cefazolin, 2 g every 8 hours, also is effective. Patients with infections due to methicillin-resistant strains of S aureus or who have severe penicillin allergies should be treated with vancomycin, 30 mg/kg/d intravenously divided in two or three doses. Doses should be adjusted to achieve a vancomycin trough of 15–20 mcg/mL. Oral step-down therapy to a rifampin combination regimen may be effective and in certain cases primary oral therapy may be effective, but consultation with an infectious diseases specialist is recommended. The role of newer agents, such as daptomycin or linezolid, remains to be defined.
3. Staphylococcal Bacteremia

*S. aureus* readily invades the bloodstream and infects sites distant from the primary site of infection, which may be relatively minor or even inapparent. Whenever *S. aureus* is recovered from blood cultures, the possibility of endocarditis, osteomyelitis, or other metastatic deep infection must be considered. Bacteremia that persists for more than 48 to 96 hours after initiation of therapy is strongly predictive of worse outcome and complicated infection. The appropriate duration of therapy for uncomplicated bacteremia arising from a removable source (eg, intravenous device) or drainable focus (eg, skin abscess) has not been well defined, but a 10- to 14-day course of therapy appears to be the minimum. However, 5% or more of patients may relapse, usually with endocarditis or osteomyelitis, even if treated for 2 weeks.

Nafcillin or oxacillin, 2 g intravenously every 4 hours or cefazolin, 2 g every 8 hours is recommended for uncomplicated methicillin-susceptible *S. aureus* bacteremia. Vancomycin, 30 mg/kg/d intravenously in two or three divided doses, as definitive therapy should be reserved for patients with serious penicillin allergy or with infections caused by methicillin-resistant strains because it is less active than β-lactam antibiotics and treatment failures are more common than with β-lactams. Maintaining a vancomycin trough concentration of 15–20 mcg/mL may improve outcomes and is recommended. Transesophageal echocardiography (TEE) is a sensitive and cost-effective method for excluding underlying endocarditis. It is considered for patients for whom the pretest probability of endocarditis is 5% or higher—and for all patients with unexplained *S. aureus* bacteremia.

Vancomycin treatment failures are relatively common, particularly for complicated bacteremia, in foreign body infection, or when the MIC of the isolate is ≥ 2 mcg/mL. Consultation should be sought with an infectious diseases specialist when vancomycin treatment failure is encountered. Daptomycin, 6 mg/kg intravenously once daily, is approved by the FDA for treatment of *S. aureus* bacteremia and is an alternative to vancomycin, especially if a β-lactam cannot be used or if the patient is not responding to vancomycin. Cases of vancomycin treatment failures in which the staphylococcal isolate exhibits a vancomycin MIC ≥ 4 mcg/mL should be reported to the Centers for Disease Control and Prevention (CDC) to help track this potentially serious and emerging problem of vancomycin resistance.

Empiric therapy of suspected staphylococcal infection, whether of community or hospital onset, depends on the severity of the infection and the likelihood that it is caused by methicillin-resistant strains. If the prevalence exceeds 5–10% for more seriously ill patients, initial therapy should include vancomycin, 30 mg/kg/d intravenously divided in two or three doses, until results of susceptibility tests are known. Resistance to vancomycin fortunately remains rare and should not affect the choice of empiric therapy.

4. Toxic Shock Syndrome

*S. aureus* produces toxins that cause three important entities: “scalded skin syndrome” in children, toxic shock syndrome in adults, and enterotoxin food poisoning. Toxic shock syndrome is characterized by abrupt onset of high fever, vomiting, and watery diarrhea. Sore throat, myalgias, and headache are common. Hypotension with kidney and heart failure is associated with a poor outcome. A diffuse macular erythematous rash (Figure 33–2) and non-purulent conjunctivitis are common, and desquamation, especially of palms and soles, is typical during recovery. Fatality rates may be as high as 15%. Although originally associated with tampon use, any focus (eg, nasopharynx, bone, vagina, rectum, abscess, or wound) harboring a toxin-producing *S. aureus* strain can cause toxic shock syndrome and nonmenstrual cases of toxic shock syndrome are common. Classically, blood cultures are negative because symptoms are due to the effects of the toxin and not systemic infection.

Important aspects of treatment include rapid rehydration, antistaphylococcal drugs, management of kidney or heart failure, and addressing sources of toxin, eg, removal of tampon or drainage of abscess.

5. Infections Caused by Coagulase-Negative Staphylococci

Coagulase-negative staphylococci are an important cause of infections of intravascular and prosthetic devices and of wound infection following cardiothoracic surgery.
These organisms infrequently cause infections such as osteomyelitis and endocarditis in the absence of a prosthesis, but rates may be increasing. Most human infections are caused by Staphylococcus epidermidis, S haemolyticus, S hominis, S warnerii, S saprophyticus, S saccharolyticus, and S cohnii. These common hospital-acquired pathogens are less virulent than S aureus, and infections caused by them tend to be more indolent.

Because coagulase-negative staphylococci are normal inhabitants of human skin, it is difficult to distinguish infection from contamination, the latter perhaps accounting for three-fourths of blood culture isolates. Infection is more likely if the patient has a foreign body (eg, sternal wires, prosthetic joint, prosthetic cardiac valve, pacemaker, intracranial pressure monitor, cerebrospinal fluid shunt, peritoneal dialysis catheter) or an intravascular device in place. Purulent or serosanguineous drainage, erythema, pain, or tenderness at the site of the foreign body or device suggests infection. Instability and pain are signs of prosthetic joint infection. Fever, a new murmur, instability of the prosthesis, or signs of systemic embolization are evidence of prosthetic valve endocarditis. Immunosuppression and recent antimicrobial therapy are risk factors.

Infection is also more likely if the same strain is consistently isolated from two or more blood cultures (particularly if samples were obtained at different times) and from the foreign body site. Contamination is more likely when a single blood culture is positive or if more than one strain is isolated from blood cultures. The antimicrobial susceptibility pattern and speciation are used to determine whether one or more strains have been isolated. More sophisticated typing methods, eg, pulse-field gel electrophoresis of restriction enzyme digested chromosomal DNA, may be required to identify distinct strains.

Whenever possible, the intravascular device or foreign body suspected of being infected by coagulase-negative staphylococci should be removed. However, removal and replacement of some devices (eg, prosthetic joint, prosthetic cardiac valve, pacemaker, cerebrospinal fluid shunt) can be a difficult or risky procedure, and it may sometimes be preferable to treat with antibiotics alone with the understanding that the probability of cure is reduced and that surgical management may eventually be necessary.

Coagulase-negative staphylococci are commonly resistant to β-lactams and multiple other antibiotics. For patients with normal kidney function, vancomycin, 1 g intravenously every 12 hours, is the treatment of choice for suspected or confirmed infection caused by these organisms until susceptibility to penicillinase-resistant penicillins or other agents has been confirmed. Duration of therapy has not been established for relatively uncomplicated infections, such as those secondary to intravenous devices, which may be eliminated by simply removing the infected device. Infection involving bone or a prosthetic valve should be treated for 6 weeks. A combination regimen of vancomycin plus rifampin, 300 mg orally twice daily, plus gentamicin, 1 mg/kg intravenously every 8 hours, is recommended for treatment of prosthetic valve endocarditis caused by methicillin-resistant strains.

### Differential Diagnosis

Other bacteria can produce gas in infected tissue, eg, enteric gram-negative organisms, or anaerobes.
3. Tetanus

**Essentials of Diagnosis**

- History of wound and possible contamination.
- Jaw stiffness followed by spasms of jaw muscles (trismus).
- Stiffness of the neck and other muscles, dysphagia, irritability, hyperreflexia.
- Finally, painful convulsions precipitated by minimal stimuli.

**General Considerations**

Tetanus is caused by the neurotoxin tetanospasmin, elaborated by *C. tetani*. Spores of this organism are ubiquitous in soil and may germinate when introduced into a wound. The vegetative bacteria produce tetanospasmin, a zinc metalloprotease that cleaves synaptobrevin, a protein essential for neurotransmitter release. Tetanospasmin interferes with neurotransmission at spinal synapses of inhibitory neurons. As a result, minor stimuli result in uncontrolled spasms, and reflexes are exaggerated. The incubation period is 5 days to 15 weeks, with the average being 8–12 days.

Most cases occur in unvaccinated individuals. Persons at risk are the elderly, migrant workers, newborns, and injection drug users. While puncture wounds are particularly prone to causing tetanus, any wound, including bites or decubiti, may become colonized and infected by *C. tetani*.

**Clinical Findings**

**A. Symptoms and Signs**

The first symptom may be pain and tingling at the site of inoculation, followed by spasticity of the muscles nearby. Stiffness of the jaw, neck stiffness, dysphagia, irritability, hyperreflexia are other early signs. Hyperreflexia develops later, with spasms of the jaw muscles (trismus) or facial muscles and rigidity and spasm of the muscles of the abdomen, neck, and back. Painful tonic convulsions precipitated by minor stimuli are common. Spasms of the glottis and respiratory muscles may cause acute asphyxia. The patient is awake and alert throughout the illness. The sensory examination is normal. The temperature is normal or only slightly elevated.

**B. Laboratory Findings**

The diagnosis of tetanus is made clinically.

**Differential Diagnosis**

Tetanus must be differentiated from various acute central nervous system infections such as meningitis. Trismus may occasionally develop with the use of phenothiazines. Strychnine poisoning should also be considered.
Complications

Airway obstruction is common. Urinary retention and constipation may result from spasms of the sphincters. Respiratory arrest and cardiac failure are late, life-threatening events.

Prevention

Tetanus is preventable by active immunization (see Table 30–7). For primary immunization of adults, Td (tetanus and diphtheria toxoids vaccine) is administered as two doses 4–6 weeks apart, with a third dose 6–12 months later. For one of the doses, Tdap (tetanus toxoid, reduced dose diphtheria toxoid, acellular pertussis vaccine) should be substituted for Td. Booster doses are given every 10 years or at the time of major injury if it occurs more than 5 years after a dose. A single dose of Tdap is preferred to Td for wound prophylaxis if the patient has not been previously vaccinated with Tdap.

Passive immunization should be used in nonimmunized individuals and those whose immunization status is uncertain whenever a wound is contaminated or likely to have devitalized tissue. Tetanus immune globulin, 250 units, is given intramuscularly. Active immunization with tetanus toxoid is started concurrently. Table 33–2 provides a guide to prophylactic management.

Treatment

A. Specific Measures

Human tetanus immune globulin, 500 units, should be administered intramuscularly within the first 24 hours of presentation. Whether intrathecal administration has any additional benefit is controversial. An unblinded, randomized trial comparing intramuscular tetanus immune globulin to intramuscular plus intrathecal tetanus immune globulin found more rapid resolution of spasms, fewer days of ventilatory support, and a shorter hospital stay in the intrathecal group. However, the exact immunoglobulin preparation that was used was not specified and the total dose was 4000 units. Tetanus does not produce natural immunity, and a full course of immunization with tetanus toxoid should be administered once the patient has recovered.

B. General Measures

Minimal stimuli can provoke spasms, so the patient should be placed at bed rest and monitored under the quietest conditions possible. Sedation, paralysis with curare-like agents, and mechanical ventilation are often necessary to control tetanic spasms. Penicillin, 20 million units intravenously daily in divided doses, is given to all patients—even those with mild illness—to eradicate toxin-producing organisms.

Prognosis

High mortality rates are associated with a short incubation period, early onset of convulsions, and delay in treatment. Contaminated lesions about the head and face are more dangerous than wounds on other parts of the body.

4. Botulism

- History of recent ingestion of home-canned or smoked foods or of injection drug use and demonstration of toxin in serum or food.
- Sudden onset of diplopia, dry mouth, dysphagia, dysphonia, and muscle weakness progressing to respiratory paralysis.
- Pupils are fixed and dilated in most cases.

1Such as, but not limited to, wounds contaminated with dirt, feces, soil, saliva, etc; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.
2Td indicates tetanus toxoid and diphtheria toxoid, adult form. Tdap indicates tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine, which may be substituted as a single dose for Td. Unvaccinated individuals should receive a complete series of three doses, one of which is Tdap.
3Human tetanus immune globulin, 250 units intramuscularly.
4Yes if more than 10 years have elapsed since last dose.
5Yes if more than 5 years have elapsed since last dose. (More frequent boosters are not needed and can enhance side effects.) Tdap has been safely administered within 2 years of Td vaccination, although local reactions to the vaccine may be increased.
General Considerations

Botulism is a paralytic disease caused by botulinum toxin, which is produced by *C. botulinum*, a ubiquitous, strictly anaerobic, spore-forming bacillus found in soil. Four toxin types—A, B, E, and F—cause human disease. Botulinum toxin is a zinc metalloprotease that cleaves a specific component of the synaptic vesicle membrane docking and fusion complex at the neuromuscular junction blocking release of the neurotransmitter acetylcholine. Botulinum toxin is extremely potent and is classified by the CDC as a high-priority agent because of its potential for use as an agent of bioterrorism. Naturally occurring botulism occurs in one of three forms: food-borne botulism, infant botulism, or wound botulism. Food-borne botulism is caused by ingestion of preformed toxin present in canned, smoked, or vacuum-packed foods such as home-canned vegetables, smoked meats, and vacuum-packed fish. Commercial foods have also been associated with outbreaks of botulism. Infant botulism (associated with ingestion of honey) and wound botulism (which typically occurs in association with injection drug use) result from organisms present in the gut or wound that elaborate toxin in vivo.

Clinical Findings

A. Symptoms and Signs

Twelve to 36 hours after ingestion of the toxin, visual disturbances appear, particularly diplopia and loss of accommodation. Ptosis, cranial nerve palsies with impairment of extraocular muscles, and fixed dilated pupils are characteristic signs. The sensory examination is normal. Other symptoms are dry mouth, dysphagia, and dysphonia. Nausea and vomiting may be present, particularly with type E toxin. The sensorium remains clear and the temperature normal. Paralysis progressing to respiratory failure and death may occur unless mechanical assistance is provided.

B. Laboratory Findings

Toxin in patients’ serum and in suspected foods can be demonstrated by mouse inoculation and identified with specific antiserum.

Differential Diagnosis

Because the clinical presentation of botulism is so distinctive and the differential diagnosis limited, botulism once considered is not easily confused with other diseases. Cranial nerve involvement may be seen with verteobasilar insufficiency, the C. Miller Fisher variant of Guillain-Barré syndrome, myasthenia gravis, or any basilar meningitis (infectious or carcinomatous). Intestinal obstruction or other types of food poisoning are considered when nausea and vomiting are present.

Treatment

If botulism is suspected, the practitioner should contact the state health authorities or the CDC for advice and help with procurement of equine serum heptavalent botulism antitoxin and for assistance in obtaining assays for toxin in serum, stool, or food. Skin testing is recommended to exclude hypersensitivity to the antitoxin preparation. Antitoxin should be administered as early as possible, ideally within 24 hours of the onset of symptoms or signs, to arrest progression of disease; its administration should not be delayed for laboratory confirmation of the diagnosis. Respiratory failure is managed with intubation and mechanical ventilation. Parenteral fluids or alimentation should be given while swallowing difficulty persists. The removal of unabsorbed toxin from the gut may be attempted. Any remnants of suspected foods should be assayed for toxin. Persons who might have eaten the suspected food must be located and observed.
multiply within the lymphatics, causing a hemorrhagic lymphadenitis. Invasion of the bloodstream leads to overwhelming sepsis, killing the host.

Clinical Findings

A. Symptoms and Signs

1. Cutaneous anthrax—This occurs within 2 weeks after exposure to spores; there is no latency period for cutaneous disease as there is with inhalational anthrax. The initial lesion is an erythematous papule, often on an exposed area of skin that vesiculates and then ulcerates and undergoes necrosis, ultimately progressing to a purple to black eschar. The eschar typically is painless; pain indicates secondary staphylococcal or streptococcal infection. The surrounding area is edematous and vesicular but not purulent. Regional adenopathy, fever, malaise, headache, and nausea and vomiting may be present. The infection is self-limited in most cases, but hematogenous spread with sepsis or meningitis may occur.

2. Inhalational anthrax—Illness occurs in two stages, beginning on average 10 days after exposure, but may have a latent onset 6 weeks after exposure. Nonspecific viral-like symptoms such as fever, malaise, headache, dyspnea, cough, and congestion of the nose, throat, and larynx are characteristic of the initial stage. Anterior chest pain is an early symptom of mediastinitis. Within hours to a few days, progression to the fulminating stage of infection occurs in which symptoms or signs of overwhelming sepsis predominate. Delirium, obtundation, or findings of meningeal irritation suggest an accompanying hemorrhagic meningitis.

3. Gastrointestinal anthrax—This form was recently reported in the United States. Fever, diffuse abdominal pain, rebound abdominal tenderness, constipation, and diarrhea occur 2–5 days after ingestion of meat contaminated with anthrax spores. The primary lesion is ulcerative, producing emesis that may be blood-tinged or coffee-ground and stool that may be blood-tinged or melena. Bowel perforation can occur. The oropharyngeal form of the disease is characterized by local lymphadenopathy, cervical edema, dysphagia, and upper respiratory tract obstruction.

B. Laboratory Findings

Laboratory findings are nonspecific. The white blood cell count initially may be normal or modestly elevated, with polymorphonuclear predominance and an increase in early forms. Pleural fluid from patients with inhalational anthrax is typically hemorrhagic with few white cells. Cerebrospinal fluid from meningitis cases is also hemorrhagic. Gram stain of pleural fluid, cerebrospinal fluid, unspun blood, blood culture, or fluid from a cutaneous lesion may show the characteristic boxcar-shaped encapsulated rods in chains.

The diagnosis is established by isolation of the organism from culture of the skin lesion (or fluid expressed from it), blood, or pleural fluid—or cerebrospinal fluid in cases of meningitis. In the absence of prior antimicrobial therapy, cultures are invariably positive. Cultures obtained after initiation of antimicrobial therapy may be negative. If anthrax is suspected on clinical or epidemiologic grounds, immunohistochemical tests (eg, to detect capsular antigen), polymerase chain reaction assays, and serologic tests (useful for documenting past cutaneous infection) are available through the CDC and should be used to establish the diagnosis. Any suspected case of anthrax should be immediately reported to the CDC so that a complete investigation can be conducted.

C. Imaging

The chest radiograph is the most sensitive test for inhalational disease, being abnormal (though the findings can be subtle) initially in every case of bioterrorism-associated disease. Mediastinal widening due to hemorrhagic lymphadenitis, a hallmark feature of the disease, has been present in 70% of the bioterrorism-related cases. Pleural effusions were present initially or occurred over the course of illness in all cases, and approximately three-fourths had pulmonary infiltrates or signs of consolidation.

Differential Diagnosis

Cutaneous anthrax, despite its characteristic appearance, can be confused with a variety of other also uncommon or rare conditions such as ecthyma gangrenosum, rat-bite fever, ulceroglandular tularemia, plague, glanders, rickettsialpox, orf (parapoxvirus infection), or cutaneous mycobacterial infection. Inhalational anthrax must be differentiated from mediastinitis due to other bacterial causes, fibrous mediastinitis due to histoplasmosis, coccidiomycosis, atypical or viral pneumonia, silicosis, sarcoidosis, and other causes of mediastinal widening (eg, superior vena cava syndrome or aortic aneurysm or dissection). Gastrointestinal anthrax shares clinical features with a variety of common intra-abdominal disorders, including bowel obstruction, perforated vescus, peritonitis, gastroenteritis, and peptic ulcer disease.

Treatment

Strains of B. anthracis (including the strain isolated in the bioterrorism cases) are susceptible in vitro to penicillin, amoxicillin, chloramphenicol, clindamycin, imipenem, doxycycline, ciprofloxacin (as well as other fluoroquinolones), macrolides, rifampin, and vancomycin. B. anthracis may express β-lactamases that confer resistance to cephalosporins and penicillins. For this reason, penicillin or amoxicillin is no longer recommended for use as a single agent in treatment of disseminated disease. Based on results of animal experiments and because of concern for engineered drug resistance in strains of B. anthracis used in bioterrorism, ciprofloxacin is considered the drug of choice (Table 33–3) for treatment and for prophylaxis following exposure to anthrax spores. Other fluoroquinolones with activity against gram-positive bacteria (eg, levofloxacin, moxifloxacin) are likely to be just as effective as ciprofloxacin. Doxycycline is an alternative first-line agent. Combination therapy with at least one additional agent is recommended for inhalational or disseminated disease and in cutaneous infection involving the face, head, and neck or associated with extensive local edema or systemic signs of

Infection, eg, fever, tachycardia and elevated white blood cell count. Single-drug therapy is recommended for prophylaxis following exposure to spores.

The required duration of therapy is poorly defined. In naturally occurring disease, treatment for 7–10 days for cutaneous disease and for at least 2 weeks following clinical response for disseminated, inhalational, or gastrointestinal infection have been standard recommendations. Because of concern about relapse from latent spores acquired by inhalation of aerosol in bioterrorism-associated cases, the initial recommendation was treatment for 60 days.

**Prevention**

In 2001, the CDC offered one of two options for postal workers receiving prophylaxis for exposure to contaminated mail: (1) antibiotics for 100 days (fearing that even with 60 days of treatment late relapses might occur) or (2) vaccination with an investigative agent (three doses administered over a 1-month period) in conjunction with 40 days of antibiotic administration to cover the time required for a protective antibody response to develop. Insufficient information exists to favor one recommendation over the other.

There is also an FDA-approved vaccine for persons at high risk for exposure to anthrax spores. The vaccine is cell-free antigen prepared from an attenuated strain of *B anthracis*. Multiple injections over 18 months and an annual booster dose are required to achieve and maintain protection. Existing supplies have been reserved for vaccination of military personnel.

**Prognosis**

The prognosis in cutaneous infection is excellent. Death is unlikely if the infection has remained localized, and lesions heal without complications in most cases. The reported mortality rate for gastrointestinal and inhalational infections is up to 85%. The experience with bioterrorism-associated inhalational cases in which six of eleven victims survived suggests a somewhat better outcome with modern supportive care and antibiotics provided that treatment is initiated before the patient has progressed to the fulminant stage of disease. No cases of anthrax have occurred among the several thousand individuals receiving antimicrobial prophylaxis following exposure to spores.

**DIPHTHERIA**

**General Considerations**

Diphtheria is an acute infection caused by *Corynebacterium diphtheriae* that usually attacks the respiratory tract but may involve any mucous membrane or skin wound. The organism is spread chiefly by respiratory secretions. Exotoxin produced by the organism is responsible for myocarditis and neuropathy. This exotoxin inhibits elongation factor, which is required for protein synthesis.

**Clinical Findings**

**A. Symptoms and Signs**

Nasal, laryngeal, pharyngeal, and cutaneous forms of diphtheria occur. Nasal infection produces few symptoms other than a nasal discharge. Laryngeal infection may lead to upper airway and bronchial obstruction. In pharyngeal diphtheria, the most common form, a tenacious gray membrane covers the tonsils and pharynx. Mild sore throat, fever, and malaise are followed by toxemia and prostration.

Myocarditis and neuropathy are the most common and most serious complications. Myocarditis causes cardiac arrhythmias, heart block, and heart failure. The neuropathy usually involves the cranial nerves first, producing diplopia, slurred speech, and difficulty in swallowing.

**B. Laboratory Findings**

The diagnosis is made clinically but can be confirmed by culture of the organism.

**Differential Diagnosis**

Diphtheria must be differentiated from streptococcal pharyngitis, infectious mononucleosis, adenovirus or herpes simplex infection, Vincent angina, pharyngitis due to...
Arcanobacterium haemolyticum, and candidiasis. A presumptive diagnosis of diphtheria should be made on clinical grounds without waiting for laboratory verification, since emergency treatment is needed.

**Prevention**

Active immunization with diphtheria toxoid is part of routine childhood immunization with appropriate booster injections. The immunization schedule for adults is the same as for tetanus.

Susceptible persons exposed to diphtheria should receive a booster dose of diphtheria toxoid (or a complete series if previously unimmunized), as well as a course of penicillin or erythromycin.

**Treatment**

Antitoxin, which is prepared from horse serum, must be given in all cases when diphtheria is suspected. For mild early pharyngeal or laryngeal disease, the dose is 20,000–40,000 units; for moderate nasopharyngeal disease, 40,000–60,000 units; for severe, extensive, or late (3 days or more) disease, 80,000–100,000 units. Diphtheria equine antitoxin can be obtained from the CDC.

Removal of membrane by direct laryngoscopy or bronchoscopy may be necessary to prevent or alleviate airway obstruction.

Either penicillin, 250 mg orally four times daily, or erythromycin, 500 mg orally four times daily, for 14 days is effective therapy, although erythromycin is slightly more effective in eliminating the carrier state. Azithromycin or clarithromycin is probably as effective as erythromycin. The patient should be isolated until three consecutive cultures at the completion of therapy have documented elimination of the organism from the oropharynx. Contacts to a case should receive erythromycin, 500 mg orally four times daily for 7 days, to eradicate carriage.

Centers for Disease Control and Prevention (CDC). Updated recommendations for use of tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine (Tdap) in pregnant women and persons who have or anticipate having close contact with an infant aged <12 months—Advisory Committee on Immunization Practices (ACIP), 2011. MMWR Morb Mortal Wkly Rep. 2011 Oct 21;60(41):1424–6. [PMID: 22012116]

**General Considerations**

_Listeria monocytogenes_ is a facultative, motile, gram-positive rod that is capable of invading several cell types and causes intracellular infection. Most cases of infection caused by _L monocytogenes_ are sporadic, but outbreaks have been traced to eating contaminated food, including unpasteurized dairy products, hot dogs, and delicatessen meats. In 2011, a multistate outbreak of _Listeria_ infection was traced to contaminated cantaloupes. This outbreak resulted in 146 infections, 30 deaths, and 1 miscarriage in a pregnant woman.

**Clinical Findings**

Five types of infection are recognized:

1. **Infection during pregnancy**, usually in the last trimester, is a mild febrile illness without an apparent primary focus. This relatively benign disease for the mother may resolve without specific therapy. However, approximately one in five pregnancies complicated by listeriosis result in spontaneous abortion or stillbirth and surviving infants are at high risk for clinical neonatal listeriosis.

2. **Granulomatosis infantisepticum** is a neonatal infection acquired in utero, characterized by disseminated abscesses, granulomas, and a high mortality rate.

3. **Bacteremia** with or without sepsis syndrome is an infection of neonates or immunocompromised adults. The presentation is of a febrile illness without a recognized source.

4. **Meningitis** caused by _L monocytogenes_ affects infants under 2 months of age as well as older adults, ranking third after meningococcus and pneumococcus as common causes of bacterial meningitis. Cerebrospinal fluid shows a **neutrophilic** pleocytosis. Adults with meningitis are often immunocompromised, and cases have been associated with HIV infection and therapy with tumor necrosis factor (TNF) inhibitors such as infliximab.

5. **Finally, focal infections**, including adenitis, brain abscess, endocarditis, osteomyelitis, and arthritis, occur rarely.

**Treatment**

Ampicillin, 8–12 g/d intravenously in four to six divided doses (the higher dose for meningitis) is considered the treatment of choice. Gentamicin, 5 mg/kg/d intravenously once or in divided doses is synergistic with ampicillin against _Listeria_ in vitro and in animal models, and the use of combination therapy may be considered during the first few days of treatment to enhance eradication of organisms. In patients with penicillin allergies, trimethoprim-sulfamethoxazole has excellent intracellular and cerebrospinal fluid penetration and is considered an appropriate alternative. The dose is 10–20 mg/kg/d intravenously of the trimethoprim component. Mortality and morbidity rates still are high. Therapy should be administered for at least 2–3 weeks. Longer durations—between 3 and 6 weeks—have been recommended for treatment of meningitis, especially in immunocompromised persons.
Endocarditis is a bacterial or fungal infection of the valvular or endocardial surface of the heart. The clinical presentation depends on the infecting organism and the valve or valves that are infected. More virulent organisms—\(S\) \textit{aureus} in particular—tend to produce a more rapidly progressive and destructive infection. Endocarditis caused by more virulent organisms often presents as an acute febrile illness and is complicated by early embolization, acute valvular regurgitation, and myocardial abscess formation. Viridans strains of streptococci, enterococci, other bacteria, yeasts, and fungi tend to cause a more subacute picture.

Underlying valvular disease, less common than in the past, is present in about 50% of cases. Valvular disease alters blood flow and produces jet effects that disrupt the endothelial surface, providing a nidus for attachment and infection of microorganisms that enter the bloodstream. Predisposing valvular abnormalities include rheumatic involvement of any valve, bicuspid aortic valves, calcific or sclerotic aortic valves, hypertrophic subaortic stenosis, mitral valve prolapse, and a variety of congenital disorders such as ventricular septal defect, tetralogy of Fallot, coarctation of the aorta, or patent ductus arteriosus. Rheumatic disease is no longer the major predisposing factor in developed countries. Regurgitation lesions are more susceptible than stenotic ones.

The initiating event in native valve endocarditis is colonization of the valve by bacteria or yeast that gain access to the bloodstream. Transient bacteremia is common during dental, upper respiratory, urologic, and lower gastrointestinal and surgical procedures. It is less common during upper gastrointestinal and gynecologic procedures. Intravascular devices are increasingly implicated as a portal of access of microorganisms into the bloodstream. A large proportion of cases of \(S\) \textit{aureus} endocarditis are attributable to healthcare-associated bacteremia.

Native valve endocarditis is usually caused by viridans streptococci, group D streptococci, \(S\) \textit{aureus}, enterococci, or HACEK organisms (an acronym for \textit{Haemophilus aphrophilus} [now \textit{Aggregatibacter aphrophilus}], \textit{Actinobacillus actinomyctecomitans} [now \textit{Aggregatibacter actinomyctecomitans}], \textit{Cardiobacterium hominis}, \textit{Eikenella corrodens}, and \textit{Kingella} species). Streptococcal species formerly accounted for the majority of native valve endocarditis cases, but the proportion of cases caused by \(S\) \textit{aureus} has been increasing, and this organism is now the leading cause. Gram-negative organisms and fungi account for a small percentage.

In injection drug users, \(S\) \textit{aureus} accounts for over 60% of all endocarditis cases and for 80–90% of cases in which the tricuspid valve is infected. Enterococci and streptococci comprise the balance in about equal proportions. Gram-negative aerobic bacilli, fungi, and unusual organisms may cause endocarditis in injection drug users.

The microbiology of prosthetic valve endocarditis also is distinctive. Early infections (ie, those occurring within 2 months after valve implantation) are commonly caused by staphylococci—both coagulase-positive and coagulase-negative—gram-negative organisms, and fungi. In late prosthetic valve endocarditis, streptococci are commonly identified, although coagulase-negative and coagulase-positive staphylococci still cause many cases.

### Clinical Findings

#### A. Symptoms and Signs

Virtually all patients have fever at some point in the illness, although it may be very low grade (<38°C) in elderly individuals and in patients with heart failure or kidney failure. Rarely, there may be no fever at all.

The duration of illness typically is a few days to a few weeks. Nonspecific symptoms are common. The initial symptoms and signs of endocarditis may be caused by direct arterial, valvular, or cardiac damage. Although a changing regurgitant murmur is significant diagnostically, it is the exception rather than the rule. Symptoms also may occur as a result of embolization, metastatic infection or immunologically mediated phenomena. These include cough; dyspnea; arthralgias or arthritis; diarrhea; and abdominal, back, or flank pain.

The characteristic peripheral lesions—petechiae (on the palate or conjunctiva or beneath the fingernails), subungual (“splinter”) hemorrhages (Figure 33–3), Osler nodes (painful, violaceous raised lesions of the fingers, toes, or feet) (Figure 33–4), Janeway lesions (painless erythematous lesions of the palms or soles), and Roth spots (exudative lesions in the retina)—occur in about 25% of patients. Strokes and major systemic embolic events are present in about 25% of patients, and tend to occur before or within the first week of antimicrobial therapy. Hematuria and proteinuria may result from emboli or immunologically mediated glomerulonephritis, which can cause kidney dysfunction.

#### B. Imaging

Chest radiograph may show evidence for the underlying cardiac abnormality and, in right-sided endocarditis, pulmonary infiltrates. The electrocardiogram is nondiagnostic,
but new conduction abnormalities suggest myocardial abscess formation. Echocardiography is useful in identifying vegetations and other characteristic features suspicious for endocarditis and may provide adjunctive information about the specific valve or valves that are infected. The sensitivity of transthoracic echocardiography is between 55% and 65%; it cannot reliably rule out endocarditis but may confirm a clinical suspicion. TEE is 90% sensitive in detecting vegetations and is particularly useful for identifying valve ring abscesses as well as prosthetic valve endocarditis.

C. Diagnostic Studies

1. Blood cultures—Blood cultures establish the diagnosis. Three sets of blood cultures at least 1 hour apart before starting antibiotics are recommended to maximize the opportunity for a microbiologic diagnosis. Approximately 5% of cases will be culture-negative, usually attributable to administration of antimicrobials prior to obtaining cultures. If antimicrobial therapy has been administered prior to obtaining cultures and the patient is clinically stable, it is reasonable to withhold further antimicrobial therapy for 2–3 days so that appropriate cultures can be obtained. Culture-negative endocarditis may also be due to a fungus, organisms that require special media for growth (eg, Legionella, Bartonella, Abiotrophia species, formerly referred to as nutritionally deficient streptococci), organisms that do not grow on artificial media (Tropheryma whippelii, or pathogens of Q fever or psittacosis), or those that are slow-growing and may require prolonged incubation (eg, Brucella, anaerobes, HACEK organisms). Bartonella quintana has emerged as an important cause of culture-negative endocarditis.

2. Modified Duke Criteria—Clinical criteria, referred to as the Modified Duke criteria, for the diagnosis of endocarditis have been proposed. Major criteria include: (1) two positive blood cultures for a microorganism that typically causes infective endocarditis or persistent bacteremia; (2) evidence of endocardial involvement documented by echocardiography (eg, definite vegetation, myocardial abscess, or new partial dehiscence of a prosthetic valve); or (3) development of a new regurgitant murmur. Minor criteria include the presence of a predisposing condition; fever ≥ 38°C; vascular phenomena, such as cutaneous hemorrhages, aneurysm, systemic emboli, pulmonary infarction; immunologic phenomena, such as glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor; and positive blood cultures not meeting the major criteria or serologic evidence of an active infection. A definite diagnosis can be made with 80% accuracy if two major criteria, one major
criterion and three minor criteria, or five minor criteria are fulfilled. A possible diagnosis of endocarditis is made if one major and one minor criterion or three minor criteria are met. If fewer criteria are found, or a sound alternative explanation for illness is identified, or the endocarditis syndrome has resolved and the patient has defervesced within 4 days, endocarditis is unlikely.

Complications

The course of infective endocarditis is determined by the degree of damage to the heart, by the site of infection (right-sided versus left-sided, aortic versus mitral valve), by the presence of metastatic foci of infection, by the occurrence of embolization, and by immunologically mediated processes. Destruction of infected heart valves is especially common and precipitous with *S. aureus* but can occur with any organism and can progress even after bacteriologic cure. The infection can also extend into the myocardium, resulting in abscesses leading to conduction disturbances, and involving the wall of the aorta, creating sinus of Valsalva aneurysms.

Peripheral embolization to the brain and myocardium may result in infarctions. Embolization to the spleen and kidneys is also common. Peripheral emboli may initiate metastatic infections or may become established in vessel walls, leading to mycotic aneurysms. Right-sided endocarditis, which usually involves the tricuspid valve, causes septic pulmonary emboli, occasionally with infarction and lung abscesses.

Prevention

In 2007, the American Heart Association made major revisions to their recommendation on antibiotic prophylaxis for infective endocarditis. The committee determined that only a few cases of infective endocarditis would be prevented by antibiotic prophylaxis for dental procedures even if the prophylactic therapy were 100% effective. Therefore, they limited their recommendations for prophylaxis to a small group of patients with predisposing congenital or valvular anomalies (Table 33–4) undergoing select dental procedures, operations involving the respiratory tract, or operations of infected skin, skin structure, or musculoskeletal tissue (Table 33–5). Current antimicrobial recommendations are given in Table 33–6.

Treatment

Empiric regimens for endocarditis while culture results are pending should include agents active against staphylococci, streptococci, and enterococci. Vancomycin 1 g every 12 hours intravenously plus ceftriaxone 2 g every 24 hours provides appropriate coverage pending definitive diagnosis.

A. Viridans Streptococci

For penicillin-susceptible viridans streptococcal endocarditis (ie, MIC ≤ 0.1 mcg/mL), penicillin G, 2–3 million units intravenously every 4 hours for 4 weeks, is recommended. The duration of therapy can be shortened to

</table>

2See Table 33–6 for prophylactic regimens.
3Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for other forms of CHD.
4Prophylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after procedure.

2 weeks if gentamicin, 1 mg/kg intravenously every 8 hours, is used with penicillin. Ceftriaxone, 2 g once daily intravenously or intramuscularly for 4 weeks, is also effective therapy for penicillin-susceptible strains and is a convenient regimen for home therapy. For the penicillin-allergic patient, vancomycin, 15 mg/kg intravenously every 12 hours for 4 weeks, is given. The 2-week regimen is not recommended for patients with symptoms of more than 3 months’ duration or with complications such as myocardial abscess or extracardiac infection. Prosthetic valve endocarditis is treated with a 6-week course of penicillin with at least 2 weeks of gentamicin.

Viridans streptococci relatively resistant to penicillin (ie, MIC > 0.1 mcg/mL but ≤ 0.5 mcg/mL) should be

in the regimen. Because aminoglycoside resistance occurs in enterococci, susceptibility should be documented. Gentamicin is the aminoglycoside of choice, because streptomycin resistance is more common and the nephrotoxicity of gentamicin is generally more easily managed than the vestibular toxicity of streptomycin. Ampicillin, 2 g intravenously every 4 hours, or penicillin G, 3–4 million units intravenously every 4 hours (or, in the penicillin-allergic patient, vancomycin, 15 mg/kg intravenously every 12 hours), plus gentamicin, 1 mg/kg intravenously every 8 hours, are recommended. The recommended duration of combination therapy is 4–6 weeks (the longer duration for patients with symptoms for more than 3 months, relapse, or prosthetic valve endocarditis), although a study from Sweden found that discontinuing the aminoglycoside before 4 weeks did not reduce efficacy. Experience is more extensive with penicillin and ampicillin than with vancomycin for treatment of enterococcal endocarditis, and penicillin and ampicillin are superior to vancomycin in vitro. Thus, whenever possible, either ampicillin or penicillin should be used.

Endocarditis caused by viridans streptococci with an MIC $>0.5$ mcg/mL or by nutritionally deficient streptococci should be treated the same as enterococcal endocarditis (see below).

### B. Other Streptococci

Endocarditis caused by *S pneumoniae*, *S pyogenes* (group A streptococcus), or groups B, C, and G streptococci is unusual. *S pneumoniae* sensitive to penicillin (MIC $<0.1$ mcg/mL) can be treated with penicillin alone, 2–3 million units intravenously every 4 hours for 4–6 weeks. Vancomycin should be effective for endocarditis caused by strains resistant to penicillin. Group A streptococcal infection can be treated with penicillin, ceftriaxone, or vancomycin for 4–6 weeks. Groups B, C, and G streptococci tend to be more resistant to penicillin than group A streptococci, and some experts have recommended adding gentamicin, 1 mg/kg intravenously every 8 hours, to penicillin for the first 2 weeks of a 4- to 6-week course. Endocarditis caused by *S bovis* is associated with liver disease and gastrointestinal abnormalities, especially colon cancer. Colonoscopy should be performed to exclude the latter.

### C. Enterococci

For enterococcal endocarditis, penicillin alone is inadequate; either streptomycin or gentamicin must be included in the regimen. Because aminoglycoside resistance occurs in enterococci, susceptibility should be documented. Gentamicin is the aminoglycoside of choice, because streptomycin resistance is more common and the nephrotoxicity of gentamicin is generally more easily managed than the vestibular toxicity of streptomycin. Ampicillin, 2 g intravenously every 4 hours, or penicillin G, 3–4 million units intravenously every 4 hours (or, in the penicillin-allergic patient, vancomycin, 15 mg/kg intravenously every 12 hours), plus gentamicin, 1 mg/kg intravenously every 8 hours, are recommended. The recommended duration of combination therapy is 4–6 weeks (the longer duration for patients with symptoms for more than 3 months, relapse, or prosthetic valve endocarditis), although a study from Sweden found that discontinuing the aminoglycoside before 4 weeks did not reduce efficacy. Experience is more extensive with penicillin and ampicillin than with vancomycin for treatment of enterococcal endocarditis, and penicillin and ampicillin are superior to vancomycin in vitro. Thus, whenever possible, either ampicillin or penicillin should be used.

Endocarditis caused by strains resistant to penicillin, vancomycin, or aminoglycosides is particularly difficult to treat. Such cases should be treated according to recent American Heart Association guidelines and managed in consultation with an infectious diseases specialist.

### D. Staphylococci

For methicillin-susceptible *S aureus*, nafcillin or oxacillin, 1.5–2 g intravenously every 4 hours for 6 weeks, is the preferred therapy. Uncomplicated tricuspid valve endocarditis probably can be treated for 2 weeks with nafcillin or oxacillin alone. For penicillin-allergic patients, cefazolin, 2 g
intravenously every 8 hours, or vancomycin, 30 mg/kg/d intravenously divided in two or three doses, may be used. For methicillin-resistant strains, vancomycin remains the preferred agent. Aminoglycoside combination regimens are probably of no benefit and in general should be avoided. The effect of rifampin with antistaphylococcal drugs is variable, and its routine use is not recommended.

Because coagulase-negative staphylococci—a common cause of prosthetic valve endocarditis—are routinely resistant to methicillin, β-lactam antibiotics should not be used for this infection unless the isolate is demonstrated to be susceptible. A combination of vancomycin, 30 mg/kg/d intravenously divided in two or three doses for 6 weeks; rifampin, 300 mg every 8 hours for 6 weeks; and gentamicin, 1 mg/kg intravenously every 8 hours for the first 2 weeks is recommended for prosthetic valve infection. If the organism is sensitive to methicillin, either nafcillin or oxacillin can be used in combination with rifampin and gentamicin. Combination therapy with nafcillin or oxacillin (vancomycin for methicillin-resistant strains or patients allergic to β-lactams), rifampin, and gentamicin is also recommended for treatment of S aureus prosthetic valve infection.

**E. HACEK Organisms**

HACEK organisms are slow-growing, fastidious gram-negative coccobacilli or bacilli (H arophilus [now A arophilus], A actinomycetemcomitans, A hominis, E corrodens, and Kingella species) that are normal oral flora and cause < 5% of all cases of endocarditis. They may produce β-lactamase, and thus the treatment of choice is ceftriaxone (or some other third-generation cephalosporin), 2 g intravenously once daily for 4 weeks. Prosthetic valve endocarditis should be treated for 6 weeks. In the penicillin-allergic patient, experience is limited, but trimethoprim-sulfamethoxazole, quinolones, and aztreonam have in vitro activity and should be considered; desensitization may be preferable.

**F. Role of Surgery**

While many cases can be successfully treated medically, operative management is frequently required. Acute heart failure unresponsive to medical therapy is an indication for valve replacement even if active infection is present, especially for aortic valve infection. Infections unresponsive to appropriate antimicrobial therapy after 7–10 days (ie, persistent fevers, positive blood cultures despite therapy) are more likely to be eradicated if the valve is replaced. Surgery is nearly always required for cure of fungal endocarditis and is more often necessary with gram-negative bacilli. It is also indicated when the infection involves the sinuses of Valsalva or produces septal abscesses. Recurrent infection with the same organism prompts an operative approach, especially with infected prosthetic valves. Continuing embolization presents a difficult problem when the infection is otherwise responding; surgery may be the proper approach. Particularly challenging is a large and fragile vegetation demonstrated by echo in the absence of embolization. Most clinicians favor an operative approach, vegetectomy with valve repair if the patient is a good candidate. Embolization after bacteriologic cure does not necessarily imply recurrence of endocarditis.

**G. Role of Anticoagulation**

Anticoagulation is contraindicated in native valve endocarditis because of an increased risk of intracerebral hemorrhage. The role of anticoagulant therapy during active prosthetic valve endocarditis is more controversial. Reversal of anticoagulation may result in thrombosis of the mechanical prosthesis, particularly in the mitral position. On the other hand, anticoagulation during active prosthetic valve endocarditis caused by S aureus has been associated with fatal intracerebral hemorrhage. One approach is to discontinue anticoagulation during the septic phase of S aureus prosthetic valve endocarditis. In patients with S aureus prosthetic valve endocarditis complicated by a central nervous system embolic event, anticoagulation should be discontinued for the first 2 weeks of therapy. Indications for anticoagulation following prosthetic valve implantation for endocarditis are the same as for patients with prosthetic valves without endocarditis (eg, nonporcine mechanical valves and valves in the mitral position).

**Response to Therapy**

If infection is caused by viridans streptococci, enterococci, or coagulase-negative staphylococci, defervescence occurs in 3–4 days on average; with S aureus or Pseudomonas aeruginosa, fever commonly persists for 9–12 days. Blood cultures should be obtained to document sterilization of the blood. Other causes of persistent fever are myocardial or metastatic abscess, sterile embolization, superimposed hospital-acquired infection, and drug reaction. Most relapses occur within 1–2 months after completion of therapy. Obtaining one or two blood cultures during this period is prudent.

BORDETELLA PERTUSSIS
INFECTION (Whooping Cough)

GENERAL CONSIDERATIONS

Pertussis is an acute infection of the respiratory tract caused by B pertussis that is transmitted by respiratory droplets. The incubation period is 7–17 days. Half of all cases occur before age 2 years. Neither immunization nor disease confers lasting immunity to pertussis. Consequently, adults are an important reservoir of the disease. In the spring of 2010, a large pertussis outbreak that resulted in many infant deaths was identified in California. Following the identification of this epidemic, the California Department of Public Health made changes to their strategy for pertussis prevention and the Advisory Committee on Immunization Practices has made preliminary changes to their recommendations as detailed below.

CLINICAL FINDINGS

The symptoms of classic pertussis last about 6 weeks and are divided into three consecutive stages. The catarrhal stage is characterized by its insidious onset, with lacrimation, sneezing, and coryza, anorexia and malaise, and a hacking night cough that becomes diurnal. The paroxysmal stage is characterized by bursts of rapid, consecutive coughs followed by a deep, high-pitched inspiration (whoop). The convalescent stage begins 4 weeks after onset of the illness with a decrease in the frequency and severity of paroxysms of cough. The diagnosis is often not considered in adults, who may not have a typical presentation. Cough persisting more than 2 weeks is suggestive. Infection may also be asymptomatic.

The white blood cell count is usually 15,000–20,000/ mcL (rarely, as high as 50,000/mcL or more), 60–80% of which are lymphocytes. The diagnosis is established by isolating the organism from nasopharyngeal culture. A special medium (eg, Bordet-Gengou agar) must be requested. Polymerase chain reaction assays for diagnosis of pertussis may be available in some clinical or health department laboratories.

PREVENTION

Acellular pertussis vaccine is recommended for all infants, combined with diphtheria and tetanus toxoids (DTaP). Infants and susceptible adults with significant exposure should receive prophylaxis with an oral macrolide (see below). In recognition of their importance as a reservoir of disease, vaccination of adolescents and adults against pertussis is recommended (see Table 30–7). The FDA licensed two tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine (Tdap) products (BOOSTRIX, GlaxoSmithKline and ADACEL, Sanofi Pasteur) in 2005. Adolescents aged 11–18 years who have completed the DTP or DTaP vaccination series should receive a single dose of either Tdap product instead of Td (tetanus and diphtheria toxoids vaccine) for booster immunization against tetanus, diphtheria, and pertussis. Either vaccine may be used in place of Td for prophylaxis of tetanus in wound management. The ADACEL vaccine is indicated as a one-time dose for booster immunization for pertussis in persons ages 11 through 64 years. Following the 2010 pertussis outbreak and review of additional data, the Advisory Committee on Immunization Practices changed their recommendations, stating that pregnant women, who had not previously received Tdap should be immunized during pregnancy, preferably during the third or late second trimester (after 20 weeks’ gestation). If not administered during pregnancy, Tdap should be administered immediately postpartum. Adults ≤ 64 years who have or who anticipate having close contact with an infant < 2 months (eg, grandparents, child-care providers, and healthcare providers) and who have not previously received Tdap should receive a single dose of Tdap. For adults > 64 years not in close contact with infants, a single dose of Tdap vaccine may be given in place of a tetanus and diphtheria toxoids (Td) vaccine, in persons who have not previously received Tdap, Postpartum women and adults who have not been previously vaccinated with Tdap and who have close contact to an infant younger than 12 months should receive a single dose of Tdap. In addition, the Advisory Committee on Immunization Practices eliminated the recommendation that a 2-year period window is needed between receiving the Td and Tdap vaccines based on data showing that there is not an increased risk of adverse events.

TREATMENT

Antibiotic treatment should be initiated in all suspected cases. Treatment options include erythromycin, 500 mg four times a day orally for 7 days; azithromycin, 500 mg orally on day 1 and 250 mg for 4 more days; or clarithromycin, 500 mg orally twice daily for 7 days. Trimethoprim-sulfamethoxazole, 160 mg–800 mg orally twice a day for 7 days, also is effective. Treatment shortens the duration of carriage and may diminish the severity of coughing paroxysms. These same regimens are indicated for prophylaxis of contacts to an active case of pertussis that are exposed within 3 weeks of the onset of cough in the index case.
OTHER BORDETELLA INFECTIONS

*Bordetella bronchiseptica* is a pleomorphic gram-negative coccobacillus causing kennel cough in dogs. On occasion it causes upper and lower respiratory infection in humans, principally HIV-infected patients. Infection has been associated with contact with dogs and cats, suggesting animal-to-human transmission. Treatment of *B bronchiseptica* infection is guided by results of in vitro susceptibility tests.

MENINGOCOCCAL MENINGITIS

**ESSENTIALS OF DIAGNOSIS**

- Fever, headache, vomiting, confusion, delirium, convulsions.
- Petechial rash of skin and mucous membranes in many.
- Neck and back stiffness with positive Kernig and Brudzinski signs is characteristic.
- Purulent spinal fluid with gram-negative intracellular and extracellular diplococci.
- Culture of cerebrospinal fluid, blood, or petechial aspiration confirms the diagnosis.

**Clinical Findings**

**A. Symptoms and Signs**

High fever, chills, and headache; back, abdominal, and extremity pains; and nausea and vomiting are typical. Rapidly developing confusion, delirium, seizures, and coma occur in some. On examination, nuchal and back rigidity are typical. Positive Kernig and Brudzinski signs (Kernig sign is pain in the hamstrings upon extension of the knee with the hip at 90-degree flexion; Brudzinski sign is flexion of the knee in response to flexion of the neck) are specific but not sensitive findings. A petechial rash appearing in the lower extremities and at pressure points is found in most cases. Petechiae may vary in size from pinpoint lesions to large ecchymoses or even skin gangrene that may later slough if the patient survives.

**B. Laboratory Findings**

Lumbar puncture typically reveals a cloudy or purulent cerebrospinal fluid, with elevated pressure, increased protein, and decreased glucose content. The fluid usually contains > 1000 cells/mL, with polymorphonuclear cells predominating and containing gram-negative intracellular diplococci. The absence of organisms in a Gram-stained smear of the cerebrospinal fluid sediment does not rule out the diagnosis. The capsular polysaccharide can be demonstrated in cerebrospinal fluid or urine by latex agglutination; this is useful in partially treated patients, though sensitivity is 60–80%. The organism is usually demonstrated by smear and culture of the cerebrospinal fluid, oropharynx, blood, or aspirated petechiae.

Disseminated intravascular coagulation is an important complication of meningococcal infection and is typically present in toxic patients with ecchymotic skin lesions.

**Differential Diagnosis**

Meningococcal meningitis must be differentiated from other meningitides. In small infants and in the elderly, fever or stiff neck is often missing, and altered mental status may dominate the picture.

Rickettsial, echovirus and, rarely, other bacterial infections (eg, staphylococcal infections, scarlet fever) also cause petechial rash.

**Prevention**

Two vaccines, meningococcal polysaccharide vaccine (MPSV4, indicated for vaccination of persons over age 55) and a conjugate vaccine (MCV4, indicated for persons aged 2–55 years) are effective for meningococcal groups A, C, Y, and W-135. The Advisory Committee on Immunization Practices recommends immunization with a dose of MCV4 for preadolescents ages 11–12 with a booster at age 16 (see Table 30–7). For ease of program implementation, persons aged 21 years or younger should have documentation of receipt of a dose of MCV4 not more than 5 years before enrollment to college. If the primary dose was administered before the sixteenth birthday,
a booster dose should be administered before enrollment. Vaccine is also recommended as a two-dose primary series administered 2 months apart for persons aged 2 through 54 years with persistent complement deficiency, persons with functional or anatomic asplenia, and for adolescents with HIV infection. All other persons at increased risk for meningococcal disease (eg, military recruits, microbiologists, or travelers to an epidemic or highly endemic country) should receive a single dose.

Eliminating nasopharyngeal carriage of meningococci is an effective prevention strategy in closed populations and to prevent secondary cases in household or otherwise close contacts. Rifampin, 600 mg orally twice a day for 2 days, ciprofloxacin, 500 mg orally once, or one intramuscular 250-mg dose of ceftriaxone is effective. A cluster of cases of fluoroquinolone-resistant meningococcal infections was recently identified in the United States. However, ciprofloxacin remains a recommended empiric agent for eradication of nasopharyngeal carriage. School and work contacts ordinarily need not be treated. Hospital contacts receive therapy only if intense exposure has occurred (eg, mouth-to-mouth resuscitation). Accidentally discovered carriers without known close contact with meningococcal disease do not require prophylactic antimicrobials.

### Treatment

Blood cultures must be obtained and intravenous antimicrobial therapy started immediately. This may be done prior to lumbar puncture in patients in whom the diagnosis is not straightforward and for those in whom MR or CT imaging is indicated to exclude mass lesions. Aqueous penicillin G is the antibiotic of choice (24 million units/24 h intravenously in divided doses every 4 hours). The prevalence of strains of *N meningitidis* with intermediate resistance to penicillin in vitro (MICs 0.1 to 1 mcg/mL) is increasing, particularly in Europe. At what level of resistance penicillin treatment failure can occur is not known. Penicillin-intermediate strains thus far remain fully susceptible to ceftriaxone and other third-generation cephalosporins used to treat meningitis, and these should be effective alternatives to penicillin. In penicillin-allergic patients or those in whom *Haemophilus influenzae* or gram-negative meningitis is a consideration, ceftriaxone, 2 g intravenously every 12 hours, should be used. Treatment should be continued in full doses by the intravenous route until the patient is afebrile for 5 days. Shorter courses—as few as 4 days if ceftriaxone is used—are also effective.

INFECTIONS CAUSED BY MORAXELLA CATARRHALIS

*M. catarrhalis* is a gram-negative aerobic coccus morphologically and biochemically similar to *Neisseria*. It causes sinusitis, bronchitis, and pneumonia. Bacteremia and meningitis have also been reported in immunocompromised patients. The organism frequently colonizes the respiratory tract, making differentiation of colonization from infection difficult. If *M. catarrhalis* is the predominant isolate, therapy is directed against it. *M. catarrhalis* typically produces β-lactamase and therefore is usually resistant to amoxicillin and amoxicillin-clavulanate. It is susceptible to amoxicillin-clavulanate, ampicillin-sulbactam, trimethoprim-sulfamethoxazole, ciprofloxacin, and second- and third-generation cephalosporins.

B. Laboratory Findings

Several laboratory abnormalities can be associated with Legionnaires disease, which include hyponatremia, elevated liver enzymes, and elevated creatine kinase. Culture of *Legionella* species onto charcoal-yeast extract agar or similar enriched media is the most sensitive method (80–90% sensitivity) for diagnosis and permits identification of infections caused by species and serotypes other than *L. pneumophila* serotype 1. Dieterle silver staining of tissue, pleural fluid, or other infected material is also a reliable method for detecting *Legionella* species. Direct fluorescent antibody stains and serologic testing are less sensitive because these will detect only *L. pneumophila* serotype 1. In addition, making a serologic diagnosis requires that the host respond with sufficient specific antibody production. Urinary antigen tests, which are targeted for detection of *L. pneumophila* serotype 1, are also less sensitive than culture.

Treatment

Azithromycin (500 mg orally once daily), clarithromycin (500 mg orally twice daily), or a fluoroquinolone (eg, levofloxacin 500 mg orally once daily), and not erythromycin, are the drugs of choice for treatment of legionellosis because of their excellent intracellular penetration and in vitro activity, as well as desirable pharmacokinetic properties that permit oral administration and once or twice daily dosing. Duration of therapy is 10–14 days, although a 21-day course of therapy is recommended for immunocompromised patients.

LEGIONNAIRES DISEASE

ESSENTIALS OF DIAGNOSIS

- Patients are often immunocompromised, smokers, or have chronic lung disease.
- Scant sputum production, pleuritic chest pain, toxic appearance.
- Chest radiograph: focal patchy infiltrates or consolidation.
- Gram stain of sputum: polymorphonuclear leukocytes and no organisms.

General Considerations

*Legionella* infection ranks among the three or four most common causes of community-acquired pneumonia and is considered whenever the etiology of a pneumonia is in question. Legionnaire disease is more common in immunocompromised persons, in smokers, and in those with chronic lung disease. Outbreaks have been associated with contaminated water sources, such as showerheads and faucets in patient rooms and air conditioning cooling towers.

Clinical Findings

A. Symptoms and Signs

Legionnaire disease is one of the atypical pneumonias, so called because a Gram-stained smear of sputum does not show organisms. However, many features of Legionnaire disease are more like typical pneumonia, with high fevers, a toxic patient, pleurisy, and grossly purulent sputum. Classically, this pneumonia is caused by *Legionella pneumophila*, though other species can cause identical disease.

GRAM-NEGATIVE BACTEREMIA & SEPSIS

Gram-negative bacteremia can originate in a number of sites, the most common being the genitourinary system, hepatobiliary tract, gastrointestinal tract, and lungs. Less common sources include intravenous lines, infusion fluids, surgical wounds, drains, and decubitus ulcers.

Patients with potentially fatal underlying conditions in the short term such as neutropenia or immunoparesis have a mortality rate of 40–60%; those with serious underlying diseases likely to be fatal in 5 years, such as solid tumors, cirrhosis, and aplastic anemia, die in 15–20% of cases; and individuals with no underlying diseases have a mortality rate of 5% or less.

Clinical Findings

A. Symptoms and Signs

Most patients have fevers and chills, often with abrupt onset. However, 15% of patients are hypothermic.
(temperature ≤ 36.4 °C) at presentation, and 5% never develop a temperature above 37.5 °C. Hyperventilation with respiratory alkalosis and changes in mental status are important early manifestations. Hypotension and shock, which occur in 20–50% of patients, are unfavorable prognostic signs.

**B. Laboratory Findings**

Neutropenia or neutrophilia, often with increased numbers of immature forms of polymorphonuclear leukocytes, is the most common laboratory abnormality in septic patients. Thrombocytopenia occurs in 50% of patients, laboratory evidence of coagulation abnormalities in 10%, and overt disseminated intravascular coagulation in 2–3%. Both clinical manifestations and the laboratory abnormalities are nonspecific and insensitive, which accounts for the relatively low rate of blood culture positivity (approximately 20–40%). If possible, three blood cultures from separate sites should be obtained in rapid succession before starting antimicrobial therapy. The chance of recovering the organism in at least one of the three blood cultures is > 99%. The false-negative rate for a single culture of 5–10 mL of blood is 30%. This may be reduced to 5–10% (albeit with a slight false-positive rate due to isolation of contaminants) if a single volume of 30 mL is inoculated into several blood culture bottles. Because blood cultures may be falsely negative, when a patient with presumed septic shock, negative blood cultures, and inadequate explanation for the clinical course responds to antimicrobials, therapy should be continued for 10–14 days.

**Treatment**

Several factors are important in the management of patients with sepsis.

**A. Removal of Predisposing Factors**

This usually means decreasing or stopping immunosuppressive medications and in certain circumstances (eg, positive blood cultures) giving granulocyte colony-stimulating factor (filgrastim; G-CSF) to the neutropenic patient.

**B. Identifying the Source of Bacteremia**

By simply finding the source of bacteremia and removing it (central venous catheter) or draining it (abscess), a fatal disease becomes easily treatable.

**C. Supportive Measures**

The use of fluids and vasopressors for maintaining blood pressure is discussed in Chapter 12; management of disseminated intravascular coagulation is discussed in Chapter 13.

**D. Antibiotics**

Antibiotics should be given as soon as the diagnosis is suspected, since delays in therapy have been associated with increased mortality rates, particularly once hypotension develops. In general, bactericidal antibiotics should be used and given intravenously to ensure therapeutic serum levels. Penetration of antibiotics into the site of primary infection is critical for successful therapy—ie, if the infection originates in the central nervous system, antibiotics that penetrate the blood-brain barrier should be used—eg, penicillin, ampicillin, chloramphenicol, and third-generation cephalosporins—but not first-generation cephalosporins or aminoglycosides, which penetrate poorly. Sepsis caused by gram-positive organisms cannot be differentiated on clinical grounds from that due to gram-negative bacteria. Therefore, initial therapy should include antibiotics active against both types of organisms.

The number of antibiotics necessary remains controversial and depends on the cause. Table 30–5 provides a guide for empiric therapy. Although a combination of antibiotics is often recommended for “synergism,” combination therapy has not been shown to be superior to a single-drug regimen with any of several broad-spectrum antibiotics (eg, a third-generation cephalosporin, piperacillin-tazobactam, carbapenem). If multiple drugs are used initially, the regimen should be modified and coverage narrowed based on the results of culture and sensitivity testing.

**E. Corticosteroids**

The role of corticosteroids in treatment of septic shock is still quite controversial. Clinical data have suggested an association between mortality in patients with septic shock and poor adrenal reserve to cosyntropin (Cortrosyn) stimulation testing. Administration of “stress doses” of hydrocortisone to patients with relative adrenal insufficiency and vasopressor-dependent septic shock was shown to reduce mortality in earlier studies. However, the CORTICUS trial, the largest randomized control trial to evaluate the effect of stress-dose hydrocortisone on mortality in septic shock, refuted these earlier findings. This study failed to demonstrate a survival benefit from the addition of stress-dose hydrocortisone, 50 mg intravenously four times a day for 5 days followed by a 6-day tapering dose regimen, in subjects with or without a normal cosyntropin stimulation test. The use of cosyntropin stimulation testing and use of stress-dose hydrocortisone in patients with septic shock are therefore not considered to be standard care.

**F. Adjunctive Therapy**

Expanded knowledge of the pathophysiology of sepsis and septic shock and recognition that cytokines play a critical role suggest novel approaches to therapy. Strategies include blocking the effects of endotoxin with anti-endotoxin monoclonal antibodies; blockade of TNF, a potent cytokine mediator of septic shock, with anti-TNF monoclonal antibody or soluble TNF receptor; use of IL-1 receptor antagonists to inhibit the proinflammatory effects of IL-1 binding to its receptor; use of corticosteroids; and blocking platelet or thrombin activation. None of these strategies have been met with improved survival. Recombinant human activated protein C (drotrecogin alfa) was once thought to
reduce mortality of septic patients. However, the PROWESS-SHOCK trial failed to show a survival benefit for patients with severe sepsis and septic shock. In October 2011, the US FDA removed recombinant human activated protein C from the market.

SALMONELLOSIS

Salmonellosis includes infection by any of approximately 2000 serotypes of salmonellae. The taxonomy of Salmonella species has been confusing. All Salmonella serotypes are members of a single species, Salmonella enterica. Human infections are caused almost exclusively by S enterica subsp enterica, of which three serotypes—typhi, typhimurium, and choleraesuis—are predominately isolated. Three clinical patterns of infection are recognized: (1) enteric fever, the best example of which is typhoid fever, due to serotype typhi; (2) acute enterocolitis, caused by serotype typhimurium, among others; and (3) the “septicemic” type, characterized by bacteremia and focal lesions, exemplified by Salmonella typhi; (2) acute enterocolitis, caused by serotype typhimurium, among others; and (3) the “septicemic” type, characterized by bacteremia and focal lesions, exemplified by infection with serotype choleraesuis. All types are transmitted by ingestion of the organism, usually from contaminated food or drink.

1. Enteric Fever (Typhoid Fever)

ESSENTIALS OF DIAGNOSIS

- Gradual onset of malaise, headache, nausea, vomiting, abdominal pain.
- Rose spots, relative bradycardia, splenomegaly, and abdominal distention and tenderness.
- Slow (stepladder) rise of fever to maximum and then slow return to normal.
- Leukopenia; blood, stool, and urine culture positive for salmonella.

General Considerations

Enteric fever is a clinical syndrome characterized by constitutional and gastrointestinal symptoms and by headache. It can be caused by any Salmonella species. The term “typhoid fever” applies when serotype typhi is the cause. Infection is transmitted by consumption of contaminated food or drink. The incubation period is 5–14 days. Salmonella is an intracellular pathogen. Infection begins when organisms breach the mucosal epithelium of the intestines by transcytosis, an organism-mediated transport process through the cell via an endocytic vesicle. Having crossed the epithelial barrier, organisms invade and replicate in macrophages in Peyer patches, mesenteric lymph nodes, and the spleen. Serotypes other than typhi usually do not cause invasive disease, presumably because they lack the necessary human-specific virulence factors. Bacteremia occurs, and the infection then localizes principally in the lymphoid tissue of the small intestine (particularly within 60 cm of the ileocecal valve). Peyer patches become inflamed and may ulcerate, with involvement greatest during the third week of disease. The organism may disseminate to the lungs, gallbladder, kidneys, or central nervous system.

Clinical Findings

A. Symptoms and Signs

During the prodromal stage, there is increasing malaise, headache, cough, and sore throat, often with abdominal pain and constipation, while the fever ascends in a stepwise fashion. After about 7–10 days, it reaches a plateau and the patient is much more ill, appearing exhausted and often prostrated. There may be marked constipation, especially early, or “pea soup” diarrhea; marked abdominal distention occurs as well. If there are no complications, the patient’s condition will gradually improve over 7–10 days. However, relapse may occur for up to 2 weeks after defervescence.

During the early prodrome, physical findings are few. Later, splenomegaly, abdominal distention and tenderness, relative bradycardia, and occasionally meningismus appear. The rash (rose spots) commonly appears during the second week of disease. The individual spot, found principally on the trunk, is a pink papule 2–3 mm in diameter that fades on pressure. It disappears in 3–4 days.

B. Laboratory Findings

Typhoid fever is best diagnosed by blood culture, which is positive in the first week of illness in 80% of patients who have not taken antimicrobials. The rate of positivity declines thereafter, but one-fourth or more of patients still have positive blood cultures in the third week. Cultures of bone marrow occasionally are positive when blood cultures are not. Stool culture is unreliable because it may be positive in gastroenteritis without typhoid fever. Relative bradycardia and leukopenia are typical.

Differential Diagnosis

Enteric fever must be distinguished from other gastrointestinal illnesses and from other infections that have few localizing findings. Examples include tuberculosis, infective endocarditis, brucellosis, lymphoma, and Q fever. Often there is a history of recent travel to endemic areas, and viral hepatitis, malaria, or amebiasis may be in the differential as well.

Complications

Complications occur in about 30% of untreated cases and account for 75% of deaths. Intestinal hemorrhage, manifested by a sudden drop in temperature and signs of shock followed by dark or fresh blood in the stool, or intestinal
perforation, accompanied by abdominal pain and tenderness, is most likely to occur during the third week. Appearance of leukocytosis and tachycardia should suggest these complications. Urinary retention, pneumonia, thrombophlebitis, myocarditis, psychosis, cholecystitis, nephritis, osteomyelitis, and meningitis are less often observed.

**Prevention**

Immunization is not always effective but should be considered for household contacts of a typhoid carrier, for travelers to endemic areas, and during epidemic outbreaks. A multiple-dose oral vaccine and a single-dose parenteral vaccine are available. Their efficacies are similar, but oral vaccine causes fewer side effects. Boosters, when indicated, should be given every 5 years and 2 years for oral and parenteral preparations, respectively.

Adequate waste disposal and protection of food and water supplies from contamination are important public health measures to prevent salmonellosis. Carriers cannot work as food handlers.

**Treatment**

**A. Specific Measures**

Several antibiotics, including ampicillin, azithromycin, chloramphenicol, third-generation cephalosporins, and trimethoprim-sulfamethoxazole all are effective for treatment of enteric fever caused by drug-susceptible strains. These drugs can be given orally or intravenously depending on the patient’s condition. Because many salmonella strains are resistant to ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole, a fluoroquinolone—such as ciprofloxacin 750 mg orally twice a day or levofloxacin 500 mg orally once daily, 5–7 days for uncomplicated enteric fever and 10–14 days for severe infection—is the agent of choice for treatment of salmonella infections. Ceftriaxone, 2 g intravenously for 7 days, is also effective. Although resistance to fluoroquinolones or cephalosporins occurs uncommonly, the prevalence appears to be increasing. When an infection is caused by a multidrug-resistant strain, select an antibiotic to which the isolate is susceptible in vitro. Alternatively, increasing the dose of ceftriaxone to 4 g/d and treating for 10–14 days or using azithromycin 500 mg orally for 7 days in uncomplicated cases may be effective.

**B. Treatment of Carriers**

Chemotherapy often is unsuccessful in eradicating the carrier state. While treatment of carriage with ampicillin, trimethoprim-sulfamethoxazole, or chloramphenicol may be successful, ciprofloxacin, 750 mg orally twice a day for 4 weeks, has proved to be highly effective. Cholecystectomy may also achieve this goal.

**Prognosis**

The mortality rate of typhoid fever is about 2% in treated cases. Elderly or debilitated persons are likely to do poorly. With complications, the prognosis is poor. Relapses occur in up to 15% of cases. A residual carrier state frequently persists in spite of chemotherapy.

**2. Salmonella Gastroenteritis**

By far the most common form of salmonellosis is acute enterocolitis caused by numerous *Salmonella* serotypes. The incubation period is 8–48 hours after ingestion of contaminated food or liquid.

Symptoms and signs consist of fever (often with chills), nausea and vomiting, cramping abdominal pain, and diarrhea, which may be grossly bloody, lasting 3–5 days. Differentiation must be made from viral gastroenteritis, food poisoning, shigellosis, amebic dysentery, and acute ulcerative colitis. The diagnosis is made by culturing the organism from the stool.

The disease is usually self-limited, but bacteremia with localization in joints or bones may occur, especially in patients with sickle cell disease.

Treatment of uncomplicated enterocolitis is symptomatic only. Malnourished or severely ill patients, those with sickle cell disease, and HIV-positive patients should be treated for 3–5 days with trimethoprim-sulfamethoxazole (one double-strength tablet twice a day), ampicillin (100 mg/kg intravenously or orally), or ciprofloxacin (750 mg orally twice a day).

**3. Salmonella Bacteremia**

*Salmonella* infection may be manifested by prolonged or recurrent fevers accompanied by bacteremia and local infection in bone, joints, pleura, pericardium, lungs, or other sites. Mycotic abdominal aortic aneurysms may also occur. Serotypes other than *typhi* usually are isolated. This complication tends to occur in immunocompromised persons and is seen in HIV-infected individuals, who typically have bacteremia without an obvious source. Treatment is the same as for typhoid fever, plus drainage of any abscesses. In HIV-infected patients, relapse is common, and lifelong suppressive therapy may be needed. Ciprofloxacin, 750 mg orally twice a day, is effective both for therapy of acute infection and for suppression of recurrence. Incidence of infections caused by drug-resistant strains may be on the rise.

**SHIGELLOSIS**

**ESSENTIALS OF DIAGNOSIS**
- Diarrhea, often with blood and mucus.
- Crampy abdominal pain and systemic toxicity.
- White blood cells in stools; organism isolated on stool culture.

**General Considerations**

*Shigella* dysentery is a common disease, often self-limited and mild but occasionally serious. *S. sonnei* is the leading cause in the United States, followed by *S. flexneri*. *S. dysenteriae* causes the most serious form of the illness. Shigellae are invasive organisms. The infective dose is $10^3$–$10^6$ organisms. There has been a rise in strains resistant to multiple antibiotics.

**Clinical Findings**

**A. Symptoms and Signs**

The illness usually starts abruptly, with diarrhea, lower abdominal cramps, and tenesmus. The diarrheal stool is often mixed with blood and mucus. Systemic symptoms are fever, chills, anorexia and malaise, and headache. The abdomen is tender. Sigmoidoscopic examination reveals an inflamed, engorged mucosa with punctate and sometimes large areas of ulceration.

**B. Laboratory Findings**

The stool shows many leukocytes and red cells. Stool culture is positive for shigellae in most cases, but blood cultures grow the organism in $<5\%$ of cases.

**Differential Diagnosis**

Bacillary dysentery must be distinguished from salmonella enterocolitis and from disease due to enterotoxigenic *Escherichia coli*, *Campylobacter*, and *Yersinia enterocolitica*. Amebic dysentery may be similar clinically and is diagnosed by finding amebas in the fresh stool specimen. Ulcerative colitis is also an important cause of bloody diarrhea.

**Complications**

Temporary disaccharidase deficiency may follow the diarrheal illness. Reactive arthritis is an uncommon complication, usually occurring in HLA-B27 individuals infected by *Shigella*. Hemolytic-uremic syndrome occurs rarely.

**Treatment**

Treatment of dehydration and hypotension is lifesaving in severe cases. The antimicrobial treatments of choice are trimethoprim-sulfamethoxazole, one double-strength tablet twice a day for 7–10 days, or a fluoroquinolone (ciprofloxacin 750 mg orally twice daily for 7–10 days, or levofloxacin, 500 mg orally once daily) for 3 days. Fluoroquinolones are contraindicated in pregnancy. Shigellae resistant to ampicillin are common, but if the isolate is susceptible, a dose of 500 mg orally four times a day is also effective. Amoxicillin, which is less effective, should not be used.

**GASTROENTERITIS CAUSED BY *ESCHERICHIA COLI***

*E. coli* causes gastroenteritis by a variety of mechanisms. Enterotoxigenic *E. coli* (ETEC) elaborates either a heat-stable or heat-labile toxin that mediates the disease. ETEC is an important cause of traveler’s diarrhea. Enteroinvasive *E. coli* (EIEC) differs from other *E. coli* bowel pathogens in that these strains invade cells, causing bloody diarrhea and dysentery similar to infection with *Shigella* species. EIEC is uncommon in the United States. Neither ETEC nor EIEC strains are routinely isolated and identified from stool cultures because there is no selective medium. Antimicrobial therapy against *Salmonella* and *Shigella*, such as ciprofloxacin 500 mg orally twice daily, shortens the clinical course, but the disease is self-limited. Shiga-toxin-producing *E. coli* (STEC) infection can result in asymptomatic carrier stage, nonbloody diarrhea, hemolytic-uremic syndrome, or thrombotic thrombocytopenic purpura. Although *E. coli* O157:H7 is responsible for most cases of STEC infection in the United States, other STEC strains (such as *E. coli* O145) have been reported to cause severe disease. *E. coli* O157:H7 has caused several outbreaks of diarrhea and hemolytic-uremic syndrome related to consumption of undercooked hamburger, unpasteurized apple juice, and spinach, while *E. coli* O145 was recently linked to the consumption of contaminated lettuce. Older individuals and young children are most affected, with hemolytic-uremic syndrome being more common in the latter group. STEC identification can be difficult and the CDC now recommends that all stools submitted for routine testing from patients with acute community-acquired diarrhea be simultaneously cultured for *E. coli* O157:H7 and tested with an assay that detects Shiga toxins to detect non O157 STEC, such as *E. coli* O145. Antimicrobial therapy does not alter the course of the disease and may increase the risk of hemolytic-uremic syndrome. Treatment is primarily supportive. Hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura occurring in association with a diarrheal illness suggests the diagnosis and should prompt evaluation for STEC. Confirmed infections should be reported to public health officials.

Cholera

**ESSENTIALS OF DIAGNOSIS**

- History of travel in endemic area or contact with infected person.
- Voluminous diarrhea.
- Stool is liquid, gray, turbid, and without fecal odor, blood, or pus (“rice water stool”).
- Rapid development of marked dehydration.
- Positive stool cultures and agglutination of vibrios with specific sera.

**General Considerations**

Cholera is an acute diarrheal illness caused by certain serotypes of *Vibrio cholerae*. The disease is toxin-mediated, and fever is unusual. The toxin activates adenyl cyclase in intestinal epithelial cells of the small intestines, producing hypersecretion of water and chloride ion and a massive diarrhea of up to 15 L/d. Death results from profound hypovolemia. Cholera occurs in epidemics under conditions of crowding, war, and famine (eg, in refugee camps) and where sanitation is inadequate. Infection is acquired by ingestion of contaminated food or water. For over a century, cholera was rarely seen in the Western Hemisphere until an outbreak occurred in Peru, starting in the early 1990s and ending by 2001; the outbreak resulted in almost 400,000 cholera cases and more than 4000 deaths. Cholera again became a rare disease in the Western Hemisphere until late 2010. A massive earthquake in Haiti in January 2010 crumbled the country’s already fragile infrastructure. Later that fall, a cholera outbreak erupted, resulting in approximately 100,000 cases and over 1000 deaths as of December 2010.

**Clinical Findings**

Cholera is characterized by a sudden onset of severe, frequent watery diarrhea (up to 1 L/h). The liquid stool is gray; turbid; and without fecal odor, blood, or pus (“rice water stool”). Dehydration and hypotension develop rapidly. Stool cultures are positive, and agglutination of vibrios with specific sera can be demonstrated.

**Prevention**

A vaccine is available that confers short-lived, limited protection and may be required for entry into or reentry after travel to some countries. It is administered in two doses 1–4 weeks apart. A booster dose every 6 months is recommended for persons remaining in areas where cholera is a hazard.

Vaccination programs are expensive and not particularly effective in managing outbreaks of cholera. When outbreaks occur, efforts should be directed toward establishing clean water and food sources and proper waste disposal.

**Treatment**

Treatment is by replacement of fluids. In mild or moderate illness, oral rehydration usually is adequate. A simple oral replacement fluid can be made from 1 teaspoon of table salt and 4 heaping teaspoons of sugar added to 1 L of water. Intravenous fluids are indicated for persons with signs of severe hypovolemia and those who cannot take adequate fluids orally. Lactated Ringer infusion is satisfactory.

Antimicrobial therapy will shorten the course of illness. Several antimicrobials are active against *V cholerae*, including tetracycline, ampicillin, chloramphenicol, trimethoprim-sulfamethoxazole, fluoroquinolones, and azithromycin. Multiple drug-resistant strains are increasingly encountered, so susceptibility testing, if available, is advisable. A single 1 g oral dose of azithromycin is effective for severe cholera caused by strains with reduced susceptibility to fluoroquinolones, but resistance is emerging to this drug as well.

**INFECTIONS CAUSED BY OTHER VIBRIO SPECIES**

Vibrios other than *V cholerae* that cause human disease are *Vibrio parahaemolyticus*, *V vulnificus*, and *V alginolyticus*. All are halophilic marine organisms. Infection is acquired by exposure to organisms in contaminated, undercooked, or raw crustaceans or shellfish and warm (> 20°C) ocean waters and estuaries. Infections are more common during the summer months from regions along the Atlantic coast and the Gulf of Mexico in the United States and from tropical waters around the world. Oysters are implicated in up to 90% of food-related cases. *V parahaemolyticus* causes an acute watery diarrhea with crampy abdominal pain and fever, typically occurring within 24 hours after ingestion of contaminated shellfish. The disease is self-limited, and antimicrobial therapy is usually not necessary. *V parahaemolyticus* may also cause cellulitis and sepsis, though these findings are more characteristic of *V vulnificus* infection.

*V vulnificus* and *V alginolyticus*—neither of which is associated with diarrheal illness—are important causes of cellulitis and primary bacteremia following ingestion of contaminated shellfish or exposure to sea water. Cellulitis with or without sepsis may be accompanied by bulla formation and necrosis with extensive soft tissue destruction, at times requiring debridement and amputation. The infection can be rapidly progressive and is particularly severe in immunocompromised individuals—especially those with cirrhosis—with death rates as high as 50%. Patients with chronic liver disease and those who are immunocompromised should be cautioned to avoid eating raw oysters.
Tetracycline at a dose of 500 mg orally four times a day for 7–10 days is the drug of choice for treatment of suspected or documented primary bacteremia or cellulitis caused by *Vibrio* species. *V. vulnificus* is susceptible in vitro to penicillin, ampicillin, cephalosporins, chloramphenicol, aminoglycosides, and fluoroquinolones, and these agents may also be effective. *V. parahaemolyticus* and *V. alginolyticus* produce β-lactamase and therefore are resistant to penicillin and ampicillin, but susceptibilities otherwise are similar to those listed for *V. vulnificus*.

INFECTIONS CAUSED BY *CAMPYLOBACTER* SPECIES

*Campylobacter* organisms are microaerophilic, motile, gram-negative rods. Two species infect humans: *Campylobacter jejuni*, an important cause of diarrheal disease, and *C. fetus subsp. fetus*, which typically causes systemic infection and not diarrhea. Dairy cattle and poultry are an important reservoir for campylobacters. Outbreaks of enteritis have been associated with consumption of raw milk. *Campylobacter* gastroenteritis is associated with fever, abdominal pain, and diarrhea characterized by loose, watery, or bloody stools. The differential diagnosis includes shigellosis, *Salmonella* gastroenteritis, and enteritis caused by *Y. enterocolitica* or invasive *E. coli*. The disease is self-limited, but its duration can be shortened with antimicrobial therapy. Either azithromycin, 1 g orally as a single dose, or ciprofloxacin, 500 mg orally twice daily for 3 days, is effective therapy. However, fluoroquinolone resistance among *C. jejuni* isolates has been increasing and susceptibility testing should be routinely performed.

*C. fetus* causes systemic infections that can be fatal, including primary bacteremia, endocarditis, meningitis, and focal abscesses. It infrequently causes gastroenteritis. Patients infected with *C. fetus* are often older, debilitated, or immunocompromised. Closely related species, collectively termed “campylobacter-like organisms,” cause bacteremia in HIV-infected individuals. Systemic infections respond to therapy with gentamicin, chloramphenicol, ceftiraxone, or ciprofloxacin. Ceftriaxone or chloramphenicol should be used to treat infections of the central nervous system because of their ability to penetrate the blood-brain barrier.

BRUCELLOSIS

**ESSENTIALS OF DIAGNOSIS**

- History of animal exposure, ingestion of unpasteurized milk or cheese.
- Insidious onset: easy fatigueability, headache, arthralgia, anorexia, sweating, irritability.
- Intermittent and persistent fever.
- Cervical and axillary lymphadenopathy; hepatosplenomegaly.
- Lymphocytosis, positive blood culture, positive serologic test.

**General Considerations**

The infection is transmitted from animals to humans. *Brucella abortus* (cattle), *B. suis* (hogs), and *B. melitensis* (goats) are the main agents. Transmission to humans occurs by contact with infected meat (slaughterhouse workers), placenta of infected animals (farmers, veterinarians), or ingestion of infected unpasteurized milk or cheese. The incubation period varies from a few days to several weeks. Brucellosis is a systemic infection that may become chronic. In the United States, brucellosis is very rare. Almost all US cases are imported from countries where brucellosis is endemic (eg, Mexico, Mediterranean Europe, Spain, South American countries).

**Clinical Findings**

**A. Symptoms and Signs**

The onset may be acute, with fever, chills, and sweats, but more often is insidious with symptoms of weakness, weight loss, low-grade fevers, sweats, and exhaustion upon minimal activity. Headache, abdominal or back pain with anorexia and constipation, and arthralgias are also common. The chronic form may assume an undulant nature, with periods of normal temperature between acute attacks; symptoms may persist for years, either continuously or intermittently.

Fever, hepatosplenomegaly, and lymphadenopathy are the most common physical findings. Infection may present with or be complicated by specific organ involvement with signs of endocarditis, meningitis, epididymitis, orchitis, arthritis (especially sacroilitis), spondylitis, or osteomyelitis.

**B. Laboratory Findings**

The organism can be recovered from cultures of blood, cerebrospinal fluid, urine, bone marrow, or other sites. Modern automated systems have shortened the time to detection of the organism in blood culture. Cultures are more likely to be negative in chronic cases. The diagnosis often is made by serologic testing. Rising serologic titers or an absolute agglutination titer of > 1:160 supports the diagnosis.
Differential Diagnosis

Brucellosis must be differentiated from any other acute febrile disease, especially influenza, tularemia, Q fever, mononucleosis, and enteric fever. In its chronic form it resembles Hodgkin disease, tuberculosis, HIV infection, malaria, and disseminated fungal infections such as histoplasmosis and coccidiodomycosis.

Complications

The most frequent complications are bone and joint lesions such as spondylitis and suppurative arthritis (usually of a single joint), endocarditis, and meningoencephalitis. Less common complications are pneumonitis with pleural effusion, hepatitis, and cholecystitis.

Treatment

Single-drug regimens are not recommended because the relapse rate may be as high as 50%. Combination regimens of two or three drugs are most effective. Regimens of doxycycline (200 mg/d orally for 6 weeks) plus rifampin (600 mg/d orally for 6 weeks) or streptomycin (1 g/d intramuscularly for 2 weeks) or gentamicin (240 mg intramuscularly once daily for 7 days) have the lowest recurrence rates. Longer courses of therapy may be required to prevent relapse of meningitis, osteomyelitis, or endocarditis.

Clinical Findings

A. Symptoms and Signs

Fever, headache, and nausea begin suddenly, and a local lesion—a papule at the site of inoculation—develops and soon ulcerates. Regional lymph nodes may become enlarged and tender and may suppurate. The local lesion may be on the skin of an extremity or in the eye. Pneumonia may develop from hematogenous spread of the organism or may be primary after inhalation of infected aerosols, which are responsible for human-to-human transmission. Following ingestion of infected meat or water, an enteric form may be manifested by gastrointestinal symptoms, stupor, and delirium. In any type of involvement, the spleen may be enlarged and tender and there may be nonspecific rashes, myalgias, and prostration.

B. Laboratory Findings

Culturing the organism from blood or infected tissue requires special media. For this reason and because cultures of \( F. \) tularensis may be hazardous to laboratory personnel, the diagnosis is usually made serologically. A positive agglutination test (> 1:80) develops in the second week after infection and may persist for several years.

Differential Diagnosis

Brucellosis must be differentiated from any other acute febrile disease, especially influenza, tularemia, Q fever, mononucleosis, and enteric fever. In its chronic form it resembles Hodgkin disease, tuberculosis, HIV infection, malaria, and disseminated fungal infections such as histoplasmosis and coccidiodomycosis.

Complications

The most frequent complications are bone and joint lesions such as spondylitis and suppurative arthritis (usually of a single joint), endocarditis, and meningoencephalitis. Less common complications are pneumonitis with pleural effusion, hepatitis, and cholecystitis.

Treatment

Single-drug regimens are not recommended because the relapse rate may be as high as 50%. Combination regimens of two or three drugs are most effective. Regimens of doxycycline (200 mg/d orally for 6 weeks) plus rifampin (600 mg/d orally for 6 weeks) or streptomycin (1 g/d intramuscularly for 2 weeks) or gentamicin (240 mg intramuscularly once daily for 7 days) have the lowest recurrence rates. Longer courses of therapy may be required to prevent relapse of meningitis, osteomyelitis, or endocarditis.
BACTERIAL & CHLAMYDIAL INFECTIONS

aspirate or pus and blood are positive but may grow slowly. In convalescing patients, an antibody titer rise may be demonstrated by agglutination tests.

**Differential Diagnosis**

The lymphadenitis of plague is most commonly mistaken for the lymphadenitis accompanying staphylococcal or streptococcal infections of an extremity, sexually transmitted diseases such as lymphogranuloma venereum or syphilis, and tularemia. The systemic manifestations resemble those of enteric or rickettsial fevers, malaria, or influenza. The pneumonia resembles other bacterial pneumonias, and the meningitis is similar to those caused by other bacteria.

**Prevention**

Avoiding exposure to rodents and fleas in endemic areas is the best prevention strategy. Drug prophylaxis may provide temporary protection for persons exposed to the risk of plague infection, particularly by the respiratory route. Doxycycline, 100 mg twice daily for 7 days, is effective. No vaccine is available at this time.

**Treatment**

Therapy should be started immediately once plague is suspected. Either streptomycin (the agent with which there is greatest experience), 1 g every 12 hours intravenously, or gentamicin, administered as a 2-mg/kg loading dose, then 1.7 mg/kg every 8 hours intravenously, is effective. Alternatively, doxycycline, 100 mg orally or intravenously, may be used. The duration of therapy is 10 days. Patients with plague pneumonia are placed in strict respiratory isolation, and prophylactic therapy is given to any person who came in contact with the patient.

**GONOCOCCAL INFECTIONS**

- Purulent and profuse urethral discharge, especially in men, with dysuria, yielding positive smear.
- Men: epididymitis, prostatitis, periurethral inflammation, proctitis.
- Women: cervicitis with purulent discharge, or asymptomatic, yielding positive culture; vaginitis, salpingitis, proctitis also occur.
- Fever, rash, tenosynovitis, and arthritis with disseminated disease.
- Gram-negative intracellular diplococci seen in a smear or cultured from any site, particularly the urethra, cervix, pharynx, and rectum.
General Considerations

Gonorrhea is caused by Neisseria gonorrhoeae, a gram-negative diplococcus typically found inside polymorphonuclear cells. It is transmitted during sexual activity and has its greatest incidence in the 15- to 29-year-old age group. The incubation period is usually 2-8 days.

Classification

A. Urethritis and Cervicitis

In men, there is initially burning on urination and a serous or milky discharge. One to 3 days later, the urethral pain is more pronounced and the discharge becomes yellow, creamy, and profuse, sometimes blood-tinged. The disorder may regress and become chronic or progress to involve the prostate, epididymis, and periurethral glands with painful inflammation. Chronic infection leads to prostatitis and urethral strictures. Rectal infection is common in homosexual men. Atypical sites of primary infection (eg, the pharynx) must always be considered. Asymptomatic infection is common and occurs in both sexes.

Gonococcal infection in women often becomes symptomatic during menses. Women may have dysuria, urinary frequency, and urgency, with a purulent urethral discharge. Vaginitis and cervicitis with inflammation of Bartholin glands are common. Infection may be asymptomatic, with only slightly increased vaginal discharge and moderate cervicitis on examination. Infection may remain as a chronic cervicitis—an important reservoir of gonococci. It can progress to involve the uterus and tubes with acute and chronic salpingitis, with scarring of tubes and sterility. In pelvic inflammatory disease, anaeorobes and chlamydiae often accompany gonococci. Rectal infection may result from spread of the organism from the genital tract or from anal coitus.

Gram stain of urethral discharge in men, especially during the first week after onset, shows gram-negative diplococci in polymorphonuclear leukocytes. Gram stain is less often positive in women. Culture has been the gold standard for diagnosis, particularly when the Gram stain is negative. Nucleic acid amplification tests for N gonorrhoeae are FDA approved for the testing of endocervical swabs, vaginal swabs, urethral swabs (men), and urine (from both men and women), and have excellent sensitivity and specificity, and have largely replaced culture. Identification of N gonorrhoeae from rectal or pharyngeal sites, blood, and in joint fluid still requires culture.

B. Disseminated Disease

Systemic complications follow the dissemination of gonococci from the primary site via the bloodstream. Two distinct clinical syndromes—either purulent arthritis or the triad of rash, tenosynovitis, and arthralgias—are commonly observed in patients with disseminated gonococcal infection, although overlap can be seen. The skin lesions can range from maculopapular to pustular or hemorrhagic, which tend to be few in number and peripherally located. The tenosynovitis is often found in the hands and wrists and feet and ankles. These unique findings can help distinguish among other infectious syndromes. The arthritis can occur in one or more joints. Gonococci are isolated by culture from less than half of patients with gonococcal arthritis. Rarely, gonococcal endocarditis or meningitis develops.

C. Conjunctivitis

The most common form of eye involvement is direct inoculation of gonococci into the conjunctival sac. In adults, this occurs by autoinoculation of a person with genital infection. The purulent conjunctivitis may rapidly progress to panophthalmitis and loss of the eye unless treated promptly. A single 1-g dose of ceftriaxone is effective.

Diagnosis

Gonococcal urethritis or cervicitis must be differentiated from nongonococcal urethritis; cervicitis or vaginitis due to Chlamydia trachomatis, Gardnerella vaginalis, Trichomonas, Candida, and many other pathogens associated with sexually transmitted diseases; and pelvic inflammatory disease, arthritis, proctitis, and skin lesions. Often, several such pathogens coexist in a patient. Reactive arthritis (urethritis, conjunctivitis, arthritis) may mimic gonorrhea or coexist with it.

Prevention

Prevention is based on education and mechanical or chemical prophylaxis. The condom, if properly used, can reduce the risk of infection. Effective drugs taken in therapeutic doses within 24 hours of exposure can abort an infection. Partner notification and referral of contacts for treatment has been the standard method used to control sexually transmitted diseases. Expedited treatment of sex partners by patient-delivered partner therapy is more effective than partner notification in reducing persistence and recurrence rates of gonorrhea and chlamydia. This strategy is being increasingly adopted as a means of disease control.

Treatment

Therapy typically is administered before antimicrobial susceptibilities are known. The choice of which regimen to use should be based on the national prevalences of antibiotic-resistant organisms. Nationwide, strains of gonococci that are resistant to penicillin, tetracycline, or ciprofloxacin have been increasingly observed. Consequently, these drugs can no longer be considered first-line therapy. All sexual partners should be treated and tested for HIV infection and syphilis, as should the patient.

A. Uncomplicated Gonorrhea

Due to increasing resistance of N gonorrhoeae to cephalosporins, the CDC has updated its treatment recommendation for gonorrhea. Treatment for gonorrhea should include a higher dose of intramuscular ceftriaxone in combination with a second drug (azithromycin or doxycycline) regardless of concern for possible secondary infection with chlamydia. For uncomplicated gonococcal infections of the
cervix, urethra, and rectum, the recommended treatment is ceftriaxone (250 mg intramuscularly) plus either azithromycin (1000 mg orally as a single dose) or doxycycline (100 mg twice daily for 7 days). When ceftriaxone is unavailable, cefixime (400 mg orally as a single dose) in combination with either azithromycin or doxycycline as above is an alternative. Fluoroquinolones are no longer recommended because of high rates of resistance. Spectinomycin, 1 g intramuscularly once, may be used for the penicillin-allergic patient but is not currently available in the United States.

Pharyngeal gonorrhea is also treated with ceftriaxone (250 mg intramuscularly) plus either azithromycin (1000 mg orally as a single dose) or doxycycline (100 mg twice daily for 7 days). All women should have a pregnancy test before a tetracycline (such as doxycycline) is prescribed.

**B. Treatment of Other Infections**

Disseminated gonococcal infection should be treated with ceftriaxone, 1 g intravenously daily, until 48 hours after improvement begins, at which time therapy may be switched to cefixime, 400 mg orally daily to complete at least 1 week of antimicrobial therapy. An oral fluoroquinolone (ciprofloxacin, 500 mg twice daily, or levofloxacin, 500 mg once daily) for 7 days also is effective, provided the isolate is susceptible. Endocarditis should be treated with ceftriaxone, 2 g every 24 hours intravenously, for at least 3 weeks. Postgonococcal urethritis and cervicitis, which are usually caused by chlamydia, are treated with a regimen of erythromycin, doxycycline, or azithromycin as described above.

Pelvic inflammatory disease requires cefoxitin, 2 g parenterally every 6 hours, or cefotetan, 2 g intravenously every 12 hours plus doxycycline 100 mg every 12 hours. Clindamycin, 900 mg intravenously every 8 hours, plus gentamicin, administered intravenously as a 2-mg/kg loading dose followed by 1.5 mg/kg every 8 hours, is also effective. Ceftriaxone 250 mg intramuscularly as a single dose (or cefoxitin, 2 g intramuscularly, plus probenecid, 1 g orally as a single dose) plus doxycycline, 100 mg twice a day for 14 days, with or without metronidazole, 500 mg twice daily for 14 days, is an effective outpatient regimen.

---

**GRANULOMA INGUINALE**

Granuloma inguinale is a chronic, relapsing granulomatous anogenital infection due to *Calymmatobacterium (Donovania) granulomatis*. The pathognomonic cell, found in tissue scrapings or secretions, is large (25–90 mcm) and contains intracytoplasmic cysts filled with bodies (Donovan bodies) that stain deeply with Wright stain.

The incubation period is 8 days to 12 weeks. The onset is insidious. The lesions occur on the skin or mucous membranes of the genitalia or perineal area. They are relatively painless infiltrated nodules that soon slough. A shallow, sharply demarcated ulcer forms, with a beefy-red friable base. Mixed sexually transmitted disease is very common. The ulcer then becomes purulent, painful, foul-smelling, and extremely difficult to treat. Superinfection with spirochete-fusiform organisms is common. The ulcer then becomes purulent, painful, foul-smelling, and extremely difficult to treat.

Several therapies are available. Because of the indolent nature of the disease, duration of therapy is relatively long. The following recommended regimens should be given for 3 weeks or until all lesions have healed: doxycycline, 100 mg orally twice daily; or azithromycin, 1 g orally once weekly; or ciprofloxacin, 750 mg orally twice daily; or erythromycin, 500 mg orally four times a day.
encephalitis, osteomyelitis, and persistent bacteremia and endocarditis have been described.

**Trench fever** is a self-limited, louse-borne relapsing febrile disease caused by *B. quintana*. The disease has occurred epidemically in louse-infested troops and civilians during wars and endemically in residents of scattered geographic areas (eg, Central America). An urban equivalent of trench fever has been described among the homeless. Humans acquire infection when infected lice feces enter sites of skin breakdown. Onset of symptoms is abrupt and fever lasts 3–5 days, with relapses. The patient complains of weakness and severe pain behind the eyes and typically in the back and legs. Lymphadenopathy, splenomegaly, and a transient maculopapular rash may appear. Subclinical infection is frequent, and a carrier state is recognized. The differential diagnosis includes other febrile, self-limited states such as dengue, leptospirosis, malaria, relapsing fever, and typhus. Recovery occurs regularly even in the absence of treatment.

**Cat-scratch disease** is an acute infection of children and young adults caused by *Bartonella henselae*. It is transmitted from cats to humans as the result of a scratch or bite. Within a few days, a papule or ulcer will develop at the inoculation site in one-third of patients. One to 3 weeks later, fever, lymphadenopathy, and malaise occur. Regional lymph nodes become enlarged, often tender, and may suppurate. Lymphadenopathy from cat scratches resembles that due to neoplasm, tuberculosis, lymphogranuloma venereum, and bacterial lymphadenitis. The diagnosis is usually made clinically. Special cultures for bartonellae, serology, or excisional biopsy, though rarely necessary, confirm the diagnosis. The biopsy reveals necrotizing lymphadenitis and is itself not specific for cat-scratch disease. Cat-scratch disease is usually self-limited, requiring no specific therapy. Encephalitis occurs rarely.

Disseminated forms of the disease—bacillary angiomatosis, peliosis hepatis, and retinitis—occur most commonly in immunocompromised patients such as persons with late stages of HIV or solid organ transplant recipients. The lesions are vasculoproliferative and histopathologically distinct from those of cat-scratch disease. Unexplained fever in patients with late stages of HIV infection is not uncommonly due to bartonellosis. *B. quintana*, the agent of trench fever, can also cause bacillary angiomatosis and persistent bacteremia or endocarditis (which will be “culture-negative” unless specifically sought), the latter two entities being associated with homelessness. Due to the fastidious nature of the organism and its special growth requirements, serologic testing (eg, demonstration of a high antibody titer in an indirect immunofluorescence assay) or nucleic acid amplification tests are often required to establish a diagnosis.

The disseminated forms of the disease (bacillary angiomatosis, peliosis hepatis, and retinitis) require a prolonged course of antibiotic therapy often in combination with a second agent. Bacteremia and endocarditis can be effectively treated with a 6-week course of doxycycline (200 mg orally or intravenously in two divided doses per day) plus either gentamicin 3 mg/kg/d intravenously or rifampin 600 mg/d orally in two divided doses. Relapse may occur.

**ANAERObic INFECTIONS**

Anaerobic bacteria comprise the majority of normal human flora. Normal microbial flora of the mouth (anaerobic spirochetes, *Prevotella*, fusobacteria), the skin (anaerobic diphtheroids), the large bowel (bacteroides, anaerobic streptococci, clostridia), and the female genitourinary tract (bacteroides, anaerobic streptococci, fusobacteria) produce disease when displaced from their normal sites into tissues or closed body spaces.

Anaerobic infections tend to be polymicrobial and abscesses are common. Pur and infected tissue often are malodorous. Septic thrombophlebitis and metastatic infection are frequent and may require incision and drainage. Diminished blood supply that favors proliferation of anaerobes because of reduced tissue oxygenation may interfere with the delivery of antimicrobials to the site of anaerobic infection. Cultures, unless carefully collected under anaerobic conditions, may yield negative results.

Important types of infections that are most commonly caused by anaerobic organisms are listed below. Treatment of all these infections consists of surgical exploration and judicious excision in conjunction with administration of antimicrobial drugs.

### 1. Head & Neck Infections

*Prevotella melaninogenica* (formerly *Bacteroides melaninogenicus*) and anaerobic spirochetes are commonly involved in periodontal infections. These organisms, fusobacteria, and peptostreptococci may cause chronic sinusitis, peritonsillar abscess, chronic otitis media, and mastoiditis. *F. necrophorum* has been recognized as a common cause of pharyngitis in adolescents and young adults. *F. necrophorum* infection has been associated with septic internal jugular thrombophlebitis (Lemierre syndrome) and cause septic pulmonary embolization. Hygiene, drainage, and surgical debridement are as important in treatment as antimicrobials. Oral anaerobic organisms have been uniformly susceptible to penicillin, but there has been a recent trend of increasing penicillin resistance, usually due to β-lactamase production. Therefore, ampicillin/sulbactam 1.5-3 g intravenously every 6 hours (if parenteral therapy is required) or amoxicillin/clavulanic acid 875/125 mg orally twice daily, or clindamycin can be used (600 mg intravenously every 8 hours or 300 mg orally every 6 hours). Antimicrobial treatment is continued for a few days after signs and symptoms of infection have resolved. Indolent, established infections (eg, mastoiditis or osteomyelitis) may require prolonged courses of therapy, eg, 4–6 weeks or longer.

2. Chest Infections

Usually in the setting of poor oral hygiene and periodontal disease, aspiration of saliva (which contains 10<sup>8</sup> anaerobic organisms per milliliter in addition to aerobes) may lead to necrotizing pneumonia, lung abscess, and empyema. Polymicrobial infection is the rule and anaerobes—particularly <i>P. melaninogenica</i>, fusobacteria, and peptostreptococci—are common etiologic agents. Most pulmonary infections respond to antimicrobial therapy alone. Percutaneous chest tube or surgical drainage is indicated for infections that do not respond to antimicrobial therapy alone.

Penicillin-resistant <i>Bacteroides fragilis</i> and <i>P. melaninogenica</i> are commonly isolated and have been associated with clinical failures. Clindamycin, 600 mg intravenously once, followed by 300 mg orally every 6–8 hours, is the treatment of choice for these infections. Metronidazole does not cover facultative streptococci, which are often present, and if used, a second agent that is active against streptococci, such as ceftriaxone 1 g intravenously or intramuscularly daily, should be added. Penicillin, 2 million units intravenously every 4 hours, followed by amoxicillin, 500 mg every 8 hours orally, is an alternative; however, increasing prevalence of β-lactamase producing organisms is a concern. Moxifloxacin, 400 mg orally or intravenously once daily, may be used. Because these infections respond slowly, a prolonged course of therapy (eg, 4–6 weeks) is generally recommended.

3. Central Nervous System

Anaerobes are a common cause of brain abscess, subdural empyema, or septic central nervous system thrombophlebitis. The organisms reach the central nervous system by direct extension from sinusitis, otitis, or mastoiditis or by hematogenous spread from chronic lung infections. Amoxicillin therapy—eg, ceftriaxone, 2 g intravenously every 12 hours, plus metronidazole, 500 mg intravenously every 8 hours—is an important adjunct to surgical drainage. Duration of therapy is 6–8 weeks but should be based on follow-up imaging. Some small multiple brain abscesses can be treated with antibiotics alone without surgical drainage.

4. Intra-abdominal Infections

In the colon there are up to 10<sup>11</sup> anaerobes per gram of content—predominantly <i>B. fragilis</i>, clostridia, and peptostreptococci. These organisms play a central role in most intra-abdominal abscesses following trauma to the colon, diverticulitis, appendicitis, or perirectal abscess and may also participate in hepatic abscess and cholecystitis, often in association with aerobic coliform bacteria. The bacteriology includes anaerobes as well as enteric gram-negative rods and on occasion enterococci. Therapy should be directed both against anaerobes and gram-negative aerobes. Agents that are active against <i>B. fragilis</i> include metronidazole, chloramphenicol, moxifloxacin, tigecycline, ertapenem, imipenem, doripenem, ampicillin-sulbactam, ticarcillin-clavulanic acid, and piperacillin-tazobactam. Resistance to cefoxitin, cefotetan, and clindamycin is increasingly encountered. Most third-generation cephalosporins have poor efficacy.

Table 33–7 summarizes the antibiotic regimens for management of moderate to moderately severe infections (eg, patient hemodynamically stable, good surgical drainage possible or established, low APACHE score, no multiple organ failure) and severe infections (eg, major peritoneal soilage, large or multiple abscesses, patient hemodynamically unstable), particularly if drug-resistant organisms are suspected. An effective oral regimen for patients able to take it is presented also.

5. Female Genital Tract & Pelvic Infections

The normal flora of the vagina and cervix includes several species of bacteroides, peptostreptococci, group B streptococci, lactobacilli, coliform bacteria, and, occasionally, spirochetes and clostridia. These organisms commonly cause genital tract infections and may disseminate from there.
While salpingitis is often caused by gonococci and chlamydiae, tubo-ovarian and pelvic abscesses are associated with anaerobes in most cases. Postpartum infections may be caused by aerobic streptococci or staphylococci, but anaerobes are often found, and the worst cases of postpartum or postabortion sepsis are associated with clostridia and bacteroides. These have a high mortality rate, and treatment requires both antimicrobials directed against anaerobes and coliforms (see above) and abscess drainage or early hysterectomy.

6. Bacteremia & Endocarditis

Anaerobic bacteremia usually originates from the gastrointestinal tract, the oropharynx, decubitus ulcers, or the female genital tract. Endocarditis due to anaerobic and microaerophilic streptococci and bacteroides originates from the same sites. Most cases of anaerobic or microaerophilic streptococcal endocarditis can be effectively treated with 12–20 million units of penicillin G daily for 4–6 weeks, but optimal therapy of other types of anaerobic bacterial endocarditis must rely on laboratory guidance. Anaerobic corynebacteria (propionibacteria), clostridia, and bacteroides occasionally cause endocarditis.

7. Skin & Soft Tissue Infections

Anaerobic infections in the skin and soft tissue usually follow trauma, inadequate blood supply, or surgery and are most common in areas that are contaminated by oral or fecal flora. These infections also occur in injection drug users and persons sustaining animal to human bites. There may be progressive tissue necrosis (Figure 33–5) and a putrid odor.

Several terms, such as bacterial synergistic gangrene, synergistic necrotizing cellulitis, necrotizing fasciitis, and non-clostridial crepitant cellulitis, have been used to classify these infections. Although there are some differences in microbiology among them, their differentiation on clinical grounds alone is difficult. All are mixed infections caused by aerobic and anaerobic organisms and require aggressive surgical debridement of necrotic tissue for cure. Surgical consultation is obligatory to assist in diagnosis and treatment.

Broad-spectrum antibiotics active against both anaerobes and gram-positive and gram-negative aerobes (eg, vancomycin plus piperacillin-tazobactam) should be instituted empirically and modified by culture results (see Table 30–5). They are given for about a week after progressive tissue destruction has been controlled and the margins of the wound remain free of inflammation.

the mouth. Interestingly, T. whippelii, the causative agent of Whipple disease, is an actinomycete and therefore is related to the species that cause actinomycosis.

**Clinical Findings**

**A. Symptoms and Signs**

1. **Cervicofacial actinomycosis**—Cervicofacial actinomycosis develops slowly. The area becomes markedly indurated, and the overlying skin becomes reddish or cyanotic. Abscesses eventually draining to the surface persist for long periods. “Sulfur granules”—masses of filamentous organisms—may be found in the pus. There is usually little pain unless there is secondary infection. Trismus indicates that the muscles of mastication are involved. Radiography may reveal bony involvement.

2. **Thoracic actinomycosis**—Thoracic involvement begins with fever, cough, and sputum production with night sweats and weight loss. Pleuritic pain may be present. Multiple sinuses may extend through the chest wall, to the heart, or into the abdominal cavity. Ribs may be involved. Radiography shows areas of consolidation and in many cases pleural effusion. Cervicofacial or thoracic disease may occasionally involve the central nervous system, most commonly brain abscess or meningitis.

3. **Abdominal actinomycosis**—Abdominal actinomycosis usually causes pain in the ileocecal region, spiking fever and chills, vomiting, and weight loss; it may be confused with Crohn disease. Irregular abdominal masses may be palpated. Pelvic inflammatory disease caused by actinomycetes has been associated with prolonged use of an intrauterine contraceptive device. Sinuses draining to the exterior may develop. CT scanning reveals an inflammatory mass extended to involve bone.

**B. Laboratory Findings**

The anaerobic, gram-positive organism may be demonstrated as a granule or as scattered branching gram-positive filaments in the pus. Anaerobic culture is necessary to distinguish actinomycetes from nocardiae because specific therapy differs for the two infections.

**Treatment**

Penicillin G is the drug of choice. Ten to 20 million units are given via a parenteral route for 4–6 weeks, followed by oral penicillin V, 500 mg four times daily. Alternatives include ampicillin, 12 g/d intravenously for 4–6 weeks followed by oral amoxicillin 500 mg three times daily or doxycycline 100 mg twice daily intravenously or orally. Therapy should be continued for weeks to months after clinical manifestations have disappeared in order to ensure cure. Surgical procedures such as drainage and resection may be beneficial.

With penicillin and surgery, the prognosis is good. The difficulties of diagnosis, however, may permit extensive destruction of tissue before the diagnosis is identified and therapy is started.

**Nocardiosis**

*Nocardia asteroides*, an aerobic filamentous soil bacterium, causes pulmonary and systemic nocardiosis. Bronchopulmonary abnormalities (eg, alveolar proteinosis) predispose to colonization, but infection is unusual unless the patient is also receiving systemic corticosteroids or is otherwise immunosuppressed.

**Clinical Findings**

Pulmonary involvement usually begins with malaise, loss of weight, fever, and night sweats. Cough and production of purulent sputum are the chief complaints. Radiography may show infiltrates accompanied by pleural effusion. The lesions may penetrate to the exterior through the chest wall, invading the ribs.

Dissemination involves any organ. Brain abscesses and subcutaneous nodules are most frequent. This is seen exclusively in immunocompromised patients.

*N. asteroides* is usually found as delicate, branching, gram-positive filaments. It may be weakly acid-fast, occasionally causing diagnostic confusion with tuberculosis. Identification is made by culture.

**Treatment**

For cutaneous infections, therapy is initiated with intravenous trimethoprim-sulfamethoxazole administered at a dosage of 5–10 mg/kg/d (based on trimethoprim) and continued with oral trimethoprim-sulfamethoxazole, one double-strength tablet twice a day. Surgical procedures such as drainage and resection may be needed as adjunctive therapy. A higher dose of 15 mg/kg/d (based on trimethoprim) should be used for disseminated or pulmonary infections. Resistance to trimethoprim-sulfamethoxazole may be increasing and initiating treatment with two drugs while awaiting antibiotic susceptibilities is reasonable in cases of disseminated or severe localized disease. Imipenem, 500 mg intravenously every 6 hours, is an alternative. Consultation with an infectious diseases expert should be considered.

Response may be slow, and therapy must be continued for at least 6 months. The prognosis in systemic nocardiosis is poor when diagnosis and therapy are delayed.

*Nocardia brasiliensis* typically causes a digital lesion—resembling herpetic whitlow—and ascending lymphangitis in normal hosts. Antimicrobial treatment is as for *N. asteroides* infection, and the prognosis is excellent.

**INFECTIONS CAUSED BY MYCOBACTERIA**

## NONTUBERCULOUS MYCOBACTERIAL DISEASES

About 10% of mycobacterial infections are caused by nontuberculous mycobacteria. Nontuberculous mycobacterial infections are among the most common opportunistic infections in advanced HIV disease. These organisms have distinctive laboratory characteristics, occur ubiquitously in the environment, are not communicable from person to person, and are often resistant to standard antituberculous drugs.

### 1. Pulmonary Infections

*Mycobacterium avium* complex (MAC) causes a chronic, slowly progressive pulmonary infection resembling tuberculosis in immunocompetent patients, who typically have underlying pulmonary disease. Susceptibility testing for macrolide-resistance should be performed on clinical isolates. Treatment of nodular or bronchiectatic pulmonary disease is clarithromycin (1000 mg orally three times per week) or azithromycin (500 mg orally three times per week) plus rifampin (600 mg orally three times per week) or ethambutol (15 mg/kg orally three times per week). Patients with fibrocavitary lung disease or severe nodular or bronchiectatic disease should receive three-drug therapy including ethambutol, and rifampin for 2 years (or 1 year after spu-
tum conversion) has been successful. *M tuberculosis* infection ("swimming pool granuloma") presents as a nodular skin lesion following exposure to nonchlorinated water. The lesions respond to therapy with clarithromycin, doxycycline, minocycline, or trimethoprim-sulfamethoxazole.

### 2. Lymphadenitis

Most cases of lymphadenitis (scrofula) in adults are caused by *M tuberculosis* and can be a manifestation of disseminated disease. In children, the majority of cases are due to nontuberculous mycobacterial species, with MAC being the most common followed by *M scrofulaceum* in the United States and *M malmoense* and *M haemophilum* in Northern Europe. *M kansasii, M bovis, M chelonae,* and *M fortuitum* are less commonly observed. Unlike disease caused by *M tuberculosis*, which requires systemic therapy for 6 months, infection with nontuberculous mycobacteria can be successfully treated by surgical excision without antituberculous therapy.

### 3. Skin & Soft Tissue Infections

Skin and soft tissue infections such as abscesses, septic arthritis, and osteomyelitis can result from direct inoculation or hematogenous dissemination or may occur as a complication of surgery. *M abscessus, M chelonae,* and *M fortuitum* are frequent causes of these types of infections. Most cases occur in the extremities and initially present as nodules. Ulceration with abscess formation often follows. The organisms are resistant to the usual antituberculosis drugs and may have susceptibility to clarithromycin, azithromycin, doxycycline, amikacin, cefoxitin, sulfonamides, imipenem, and ciprofloxacin. Given the multidrug resistant nature of these organisms, obtaining antibiotic susceptibility testing is recommended. Therapy often includes surgical debride-
ment along with at least two active antibiotics. Antibiotic therapy is usually continued for 3 months, although this must be determined based on clinical response.

### 4. Disseminated Mycobacterium avium Infection

MAC causes disseminated disease in immunocompromised patients, most commonly in patients in the late stages of HIV infection, when the CD4 cell count is < 50/mcL. Persistent fever and weight loss are the most common symptoms. The organism can usually be cultured from multiple sites, including blood, liver, lymph node, or bone marrow. Blood culture is the preferred means of establishing the diagnosis and has a sensitivity of 98%.

#### Treatment

Agents with proved activity against MAC are rifabutin, azithromycin, clarithromycin, and ethambutol. Amikacin and ciprofloxacin work in vitro, but clinical results are inconsistent. A combination of two or more active agents should be used to prevent rapid emergence of secondary resistance. Clarithromycin, 500 mg orally twice daily, plus ethambutol, 15 mg/kg/d orally as a single dose, with or without rifabutin, 300 mg/d orally, is the treatment of choice. Azithromycin, 500 mg orally once daily, may be used instead of clarithromycin. Insufficient data are available to permit specific recommendations about second-line regimens for patients intolerant of macrolides or those with macrolide-resistant organisms. MAC therapy may be
discontinued in patients who have been treated with 12 months of therapy for disseminated MAC, who have no evidence of active disease, and whose CD4 counts exceed 100 cells/mL for 6 months while receiving highly active antiretroviral therapy (HAART).

**Prevention**

Antimicrobial prophylaxis of MAC prevents disseminated disease and prolongs survival. It is the standard of care to offer it to all HIV-infected patients with CD4 counts ≤ 50/μL. In contrast to active infection, single-drug oral regimens of clarithromycin, 500 mg twice daily, azithromycin, 1200 mg once weekly, or rifabutin, 300 mg once daily, are appropriate. Clarithromycin or azithromycin is more effective and better tolerated than rifabutin, and therefore preferred. Primary prophylaxis for MAC infection can be stopped in patients who have responded to antituberculosis combination therapy with elevation of CD4 counts > 100 cells/μL for 3 months.

**Clinical Findings**

**A. Symptoms and Signs**

The onset is usually gradual, with listlessness, irritability, anorexia, and fever, followed by headache, vomiting, convulsions, and coma. In older patients, headache and behavioral changes are prominent early symptoms. Nuchal rigidity and cranial nerve palsies occur as the meningitis progresses. Evidence of active tuberculosis elsewhere or a history of prior tuberculosis is present in up to 75% of patients.

**B. Laboratory Findings**

The spinal fluid is frequently yellowish, with increased pressure, 100–500 cells/μL (predominantly lymphocytes, though neutrophils may be present early during infection), increased protein, and decreased glucose. Acid-fast stains of cerebrospinal fluid usually are negative, and cultures also may be negative in 15–25% of cases. Nucleic acid amplification tests for rapid diagnosis of tuberculosis have variable sensitivity and specificity and none are FDA-approved for use in meningitis. Chest X-ray often reveals abnormalities compatible with tuberculosis but may be normal.

**Differential Diagnosis**

Tuberculous meningitis may be confused with any other type of meningitis, but the gradual onset, the predominantly lymphocytic pleocytosis of the spinal fluid, and evidence of tuberculosis elsewhere often point to the diagnosis. The tuberculin skin test is usually (not always) positive. Fungal and other granulomatous meningitides, syphilis, and carcinomatous meningitis are in the differential diagnosis.

**Complications**

Complications of tuberculous meningitis include seizure disorders, cranial nerve palsies, stroke, and obstructive hydrocephalus with impaired cognitive function. These result from inflammatory exudate primarily involving the basilar meninges and arteries.

**Treatment**

Presumptive diagnosis followed by early, empiric antituberculous therapy is essential for survival and to minimize sequelae. Even if cultures are not positive, a full course of therapy is warranted if the clinical setting is suggestive of tuberculosis meningitis.

Regimens that are effective for pulmonary tuberculosis are effective also for tuberculous meningitis (see Table 9–18). Rifampin, isoniazid, and pyrazinamide all
The disease is divided clinically and by laboratory tests into two distinct types: lepromatous and tuberculoid. The onset is insidious. The lesions involve the cooler body tissues: skin, superficial nerves, nose, pharynx, larynx, eyes, and testicles. Skin lesions may occur as pale, anesthetic macular—or nodular and erythematous—skin lesions. Superficial nerve thickening with associated anesthesia. History of residence in endemic area in childhood. Acid-fast bacilli in skin lesions or nasal scrapings, or characteristic histologic nerve changes. Pale, anesthetic macular—or nodular and erythematous—skin lesions. Superficial nerve thickening with associated anesthesia. History of residence in endemic area in childhood. Acid-fast bacilli in skin lesions or nasal scrapings, or characteristic histologic nerve changes.

General Considerations

Leprosy (Hansen disease) is a chronic infectious disease caused by the acid-fast rod *M. leprae*. The mode of transmission probably is respiratory and involves prolonged exposure in childhood. The disease is endemic in tropical and subtropical Asia, Africa, Central and South America, and the Pacific regions, and rarely seen sporadically in the southern United States.

Clinical Findings

A. Symptoms and Signs

The onset is insidious. The lesions involve the cooler body tissues: skin, superficial nerves, nose, pharynx, larynx, eyes, and testicles. Skin lesions may occur as pale, anesthetic macular lesions 1–10 cm in diameter; discrete erythematous, infiltrated nodules 1–5 cm in diameter; or diffuse skin infiltration. Neurologic disturbances are caused by nerve infiltration and thickening, with resultant anesthesia, and motor abnormalities. Bilateral ulnar neuropathy is highly suggestive. In untreated cases, disfigurement due to the skin infiltration and nerve involvement may be extreme, leading to trophic ulcers, bone resorption, and loss of digits. The disease is divided clinically and by laboratory tests into two distinct types: lepromatous and tuberculoid. The *lepromatous* type (also referred to as multibacillary leprosy) occurs in persons with defective cellular immunity. The course is progressive and malignant, with nodular skin lesions; slow, symmetric nerve involvement; abundant acid-fast bacilli in the skin lesions; and a negative lepromin skin test. In the *tuberculoid* type (paucibacillary leprosy), cellular immunity is intact and the course is more benign and less progressive, with macular skin lesions, severe asymmetric nerve involvement of sudden onset with few bacilli present in the lesions, and a positive lepromin skin test. Intermediate (“borderline”) cases are frequent. Eye involvement (keratitis and iridocyclitis), nasal ulcers, epistaxis, anemia, and lymphadenopathy may occur.

B. Laboratory Findings

Laboratory confirmation of leprosy requires the demonstration of acid-fast bacilli in a skin biopsy. Biopsy of skin or of a thickened involved nerve also gives a typical histologic picture. *M. leprae* does not grow in artificial media but does grow in the foot pads of armadillos.

Differential Diagnosis

The skin lesions of leprosy often resemble those of lupus erythematosus, sarcoidosis, syphilis, erythema nodosum, erythema multiforme, cutaneous tuberculosis, and vitiligo.

Complications

Kidney failure and hepatomegaly from secondary amyloidosis may occur with long-standing disease.

Treatment

Combination therapy is recommended for treatment of all types of leprosy. Single-drug treatment is accompanied by emergence of resistance, and primary resistance to dapsone also occurs. For borderline and lepromatous cases (ie, multibacillary disease), the World Health Organization recommends a triple oral drug-regimen of rifampin, 600 mg once a month; dapsone, 100 mg daily; and clofazimine, 300 mg once a month and 50 mg daily for 12 months although longer courses may be needed for patients with high burden of disease. For indeterminate and tuberculoid leprosy (paucibacillary disease), the recommendation is rifampin, 600 mg once a month, plus dapsone, 100 mg daily for 6 months.

Two reactional states—erythema nodosum lepromus and reversal reactions—may occur as a consequence of therapy. The reversal reaction, typical of borderline lepromatous leprosy, probably results from enhanced host immunity. Skin lesions and nerves become swollen and tender, but systemic manifestations are not seen. Erythema nodosum lepromus, typical of lepromatous leprosy, is a consequence of immune injury from antigen-antibody complex deposition in skin and other tissues; in addition to skin and nerve manifestations, fever and systemic involvement may be seen. Prednisone, 60 mg/d orally, or thalidomide, 300 mg/d orally (in the nonpregnant patient only), is effective for erythema nodosum lepromus. Improvement is expected within a few days after initiating prednisone, and
Chlamydiae is a family of obligate intracellular parasites closely related to gram-negative bacteria. They include two important genera of human pathogens—Chlamydia, which includes the species \( \text{C. trachomatis} \), and Chlamydiophila, which include the species \( \text{C. psittaci} \) (formerly known as \( \text{C. psittaci} \)) and \( \text{C. pneumoniae} \) (formerly known as \( \text{C. pneu-}

\text{moniae} \)). The differentiation of genera is based on differences in intracellular inclusions, sulfonamide susceptibility, antigenic composition, and disease production. \( \text{C. trachom}

\text{atis} \) causes many different human infections involving the eye (trachoma, inclusion conjunctivitis), the genital tract (lymphogranuloma venereum, nongonococcal urethritis, cervicitis, salpingitis), or the respiratory tract in infants (pneumonitis). \( \text{C. psittaci} \) causes psittacosis and \( \text{C. pneumoniae} \) is a cause of respiratory tract infections.

**CHLAMYDIA TRACHOMATIS INFECTIONS**

1. Lymphogranuloma Venereum

**ESSENTIALS OF DIAGNOSIS**

- **General Considerations**
  
  Lymphogranuloma venereum (LGV) is an acute and chronic sexually transmitted disease caused by \( \text{C. trachomatis} \) types L1–L3. The disease is acquired during intercourse or through contact with contaminated exudate from active lesions. The incubation period is 3–21 days. After the genital lesion disappears, the infection spreads to lymph channels and lymph nodes of the genital and rectal areas. Inapparent infections and latent disease are not uncommon.

- **Clinical Findings**
  
  **A. Symptoms and Signs**
  
  In men, the initial vesicular or ulcerative lesion (on the external genitalia) is evanescent and often goes unnoticed. Inguinal buboes appear 1–4 weeks after exposure, are often bilateral, and have a tendency to fuse, soften, and break down to form multiple draining sinuses, with extensive scarring. In women, the genital lymph drainage is to the perirectal glands. Early anorectal manifestations are proctitis with tenesmus and bloody purulent discharge; late manifestations are chronic cicatrizating inflammation of the rectal and perirectal tissue. These changes lead to obstruction and rectal stricture and, occasionally, rectovaginal and perianal fistulas. They are also seen in homosexual men.

**B. Laboratory Findings**

The complement fixation test may be positive (titers > 1:64), but cross-reaction with other chlamydial occurs. Although a positive reaction may reflect remote infection, high titers usually indicate active disease. Nucleic acid detection tests are sensitive, but not FDA-approved for rectal specimens and cannot differentiate LGV from non-LGV strains.

- **Differential Diagnosis**
  
  The early lesion of LGV must be differentiated from the lesions of syphilis, genital herpes, and chancroid; lymph node involvement must be distinguished from that due to tularemia, tuberculosis, plague, neoplasm, or pyogenic infection; and rectal stricture must be distinguished from that due to neoplasm and ulcerative colitis.

- **Treatment**
  
  If diagnostic testing for LGV is not available, patients with a clinical presentation suggestive of LGV should be treated empirically. The antibiotic of choice is doxycycline (contraindicated in pregnancy), 100 mg orally twice daily for 21 days. Erythromycin, 500 mg orally four times a day for 21 days, is also effective. Azithromycin, 1 g orally once weekly for 3 weeks, may also be effective.

---

an important cause of postgonococcal urethritis. Coinfection with gonococci and chlamydiae is common, and postgonoccal (ie, chlamydial) urethritis may persist after successful treatment of the gonococcal component. Occasionally, epididymitis, prostatitis, or proctitis is caused by chlamydial infection. Chlamydiae are a leading cause of infertility in females in the United States.

**Clinical Findings**

**A. Symptoms and Signs**

Females infected with chlamydiae may be asymptomatic or may have symptoms and signs of cervicitis, salpingitis, or pelvic inflammatory disease. The urethral or cervical discharge due to *C. trachomatis* tends to be less painful, less purulent, and watery compared with gonococcal infection.

**B. Laboratory Findings**

A patient with urethritis or cervicitis and absence of gram-negative diplococci on Gram stain and of *N. gonorrhoeae* on culture is assumed to have chlamydial infection until proven otherwise. The diagnosis should be confirmed, whenever possible, by the FDA-approved, highly sensitive nucleic acid amplification tests for use with urine or vaginal swabs. A negative nucleic acid amplification test for chlamydia reliably excludes the diagnosis of chlamydial urethritis or cervicitis and therapy need not be administered.

**C. Screening**

Active screening for chlamydial infection is recommended in certain settings: pregnant women; all sexually active women 25 years of age and under; older women with risk factors for sexually transmitted diseases; and men with risk factors for sexually transmitted diseases, such as HIV-positive men or men who have sex with men.

**Treatment**

Recommended regimens are a single oral 1-g dose of azithromycin (preferred and safe in pregnancy), 100 mg of doxycycline orally for 7 days (contraindicated in pregnancy), or 500 mg of levofloxacin once daily for 7 days (also contraindicated in pregnancy). Presumptively administered therapy still may be indicated for some patients (such as for an individual with gonococcal infection in whom no chlamydial testing was performed or a test other than a nucleic acid amplification test was used to exclude the diagnosis, or an individual for whom a test result is pending but is considered unlikely to follow-up, and for sexual contacts of documented cases). As for all patients in whom sexually transmitted diseases are diagnosed, studies for HIV and syphilis should also be performed.

---

**CHLAMYDOPHILA PSITTACI & PSITTACOSIS (Ornithosis)**

**Essentials of Diagnosis**

- Fever, chills, and cough; headache common.
- Atypical pneumonia with slightly delayed appearance of signs of pneumonitis.
- Contact with infected bird (psittacine, pigeons, many others) 7–15 days previously.
- Isolation of chlamydiae or rising titer of complement-fixing antibodies.

**General Considerations**

Psittacosis is acquired from contact with birds (parrots, parakeets, pigeons, chickens, ducks, and many others), which may or may not be ill. The history may be difficult to obtain if the patient acquired infection from an illegally imported bird.

**Clinical Findings**

The onset is usually rapid, with fever, chills, myalgia, dry cough, and headache. Signs include temperature-pulse dissociation, dullness to percussion, and rales. Pulmonary findings may be absent early. Dyspnea and cyanosis may occur later. Endocarditis, which is culture-negative, may occur. The radiographic findings in typical psittacosis are those of atypical pneumonia, which tends to be interstitial and diffuse in appearance, though consolidation can occur. Psittacosis is indistinguishable from other bacterial or viral pneumonias by radiography.

The organism is rarely isolated from cultures. The diagnosis is usually made serologically; antibodies appear during the second week and can be demonstrated by complement fixation or immunofluorescence. Antibody response may be suppressed by early chemotherapy.

**Differential Diagnosis**

The illness is indistinguishable from viral, mycoplasmal, or other atypical pneumonias except for the history of contact with birds. Psittacosis is in the differential diagnosis of culture-negative endocarditis.

**Treatment**

Treatment consists of giving tetracycline, 0.5 g orally every 6 hours or 0.5 g intravenously every 12 hours, for 14–21 days. Erythromycin, 500 mg orally every 6 hours, may be effective as well.

**CHLAMYDOPHILA PNEUMONIAE INFECTION**

*C. pneumoniae* causes pneumonia and bronchitis. The clinical presentation of pneumonia is that of an atypical pneumonia. The organism accounts for approximately 10% of community-acquired pneumonias, ranking second
to mycoplasma as an agent of atypical pneumonia. A putative role in coronary artery disease has not held up to close scientific scrutiny.

Like C. psittaci, strains of C. pneumoniae are resistant to sulfonamides. Erythromycin or tetracycline, 500 mg orally four times a day for 10–14 days, appears to be effective therapy. Fluoroquinolones, such as levofloxacin (500 mg once daily for 7–14 days) or moxifloxacin (400 mg once daily for 7–14 days), are active in vitro against C. pneumoniae and probably are effective. It is unclear if empiric coverage for atypical pathogens in hospitalized patients with community-acquired pneumonia provides a survival benefit or improves clinical outcome.

Syphilis is a complex infectious disease caused by *Treponema pallidum*, a spirochete capable of infecting almost any organ or tissue in the body and causing protean clinical manifestations (Table 34–1). Transmission occurs most frequently during sexual contact (including oral sex), through minor skin or mucosal lesions; sites of inoculation are usually genital but may be extragenital. The risk of acquiring syphilis after unprotected sex with an individual with infectious syphilis is approximately 30–50%. Rarely, it can also be transmitted through nonsexual contact, blood transfusion, or via the placenta from mother to fetus (congenital syphilis).

The natural history of acquired syphilis is generally divided into two major clinical stages: early (infectious) syphilis and late syphilis. The two stages are separated by a symptom-free latent phase during the first part of which (early latency) infectious lesions can recur. Infectious syphilis includes the primary lesions (chancre and regional lymphadenopathy), the secondary lesions (commonly involving skin and mucous membranes, occasionally bone, central nervous system, or liver), relapsing lesions during early latency, and congenital lesions. The hallmark of these lesions is an abundance of spirochetes; tissue reaction is usually minimal. Late syphilis consists of so-called benign (gummatous) lesions involving skin, bones, and viscera; cardiovascular disease (principally aortitis); and a variety of central nervous system and ocular syndromes. These forms of syphilis are not contagious. The lesions contain few demonstrable spirochetes, but tissue reactivity (vasculitis, necrosis) is severe and suggestive of hypersensitivity phenomena.

Public health efforts to control syphilis focus on the diagnosis and treatment of early (infectious) cases and their partners.

Most cases of syphilis in the United States continue to occur in men who have sex with men (MSM). From 2009 to 2010, the rates of primary and secondary syphilis increased in white and Hispanic men and decreased in black men and in white, black, and Hispanic women. The highest rates were in black men, however, with 34 cases/100,000 population. In 2010, 46% of the primary and secondary syphilis cases were reported from the South. The rate of congenital syphilis cases decreased between 2009 and 2010 to 9 cases/100,000 live births. Despite the increase in primary and secondary syphilis in MSM in certain urban areas, such as San Francisco, a concomitant increase in the incidence of HIV has not been observed.

**COURSE & PROGNOSIS**

The lesions associated with primary and secondary syphilis are self-limiting, even without treatment, and resolve with few or no residua. Late syphilis may be highly destructive and permanently disabling and may lead to death. Many experts now believe that while infection is almost never completely eradicated in the absence of treatment, most infections remain latent without sequelae, and only a small number of latent infections progress to further disease.

**CLINICAL STAGES OF SYphilis**

**1. Primary Syphilis**

**ESSENTIALS OF DIAGNOSIS**

- History of sexual contact (may be unreliable).
- Painless ulcer on genitalia, perianal area, rectum, pharynx, tongue, lip, or elsewhere.
- Nontender enlargement of regional lymph nodes.
- Fluid expressed from lesion contains *T. pallidum* by immunofluorescence or darkfield microscopy.
- Serologic nontreponemal and treponemal tests.

Clinical Findings

A. Symptoms and Signs

This is the stage of invasion and may pass unrecognized. The typical lesion is the chancre at the site or sites of inoculation, most frequently located on the penis (Figure 34–1), labia, cervix, or anorectal region. Anorectal lesions are especially common among MSM. Chancre also occurs occasionally in the oropharynx (lip, tongue, or tonsil) and rarely on the breast or finger. An initial small erosion 10–90 days (average, 3–4 weeks) after inoculation appears then rapidly develops into a painless superficial ulcer with a clean base and firm, indurated margins. This is associated with enlargement of regional lymph nodes, which are rubbery, discrete, and nontender. Bacterial infection of the chancre may occur and may lead to pain. Healing occurs without treatment, but a scar may form, especially with secondary bacterial infection. Multiple chancres may be present, particularly in HIV-positive patients. Although the “classic” ulcer of syphilis has been described as nontender, nonpurulent, and indurated, only 31% of patients have this triad.

B. Laboratory Findings

1. Microscopic examination—In early (infectious) syphilis, darkfield microscopic examination by a skilled observer of fresh exudate from lesions or material aspirated from regional lymph nodes is up to 90% sensitive for diagnosis. The darkfield examination requires expertise for proper specimen collection and identification of characteristic features of morphology and motility of pathogenic spirochetes, and repeated examinations may be necessary. Therefore, this testing is usually only available in select sexually transmitted disease clinics. Darkfield examination of oral lesions is not recommended because of the presence of nonpathogenic treponemes in the mouth. Spirochetes usually are not found in late syphilitic lesions by this technique.

1Based on untreated cases.

CIA, chemiluminescence assay; EIA, enzyme immunoassay; FTA-ABS, fluorescent treponemal antibody absorption assay; MHA-TP, microhemagglutination assay for T. pallidum; RPR, rapid plasma reagin test; TPPA, T. pallidum particle agglutination; VDRL, Venereal Disease Research Laboratory test.

An immunofluorescent staining technique for demonstrating T. pallidum in dried smears of fluid taken from early syphilitic lesions is available through some state health department laboratories but is not widely used. Slides are fixed and treated with fluorescein-labeled antitreponemal antibody that has been preabsorbed with nonpathogenic treponemes. The slides are then examined for fluorescing spirochetes in an ultraviolet microscope. Because of its simplicity, high specificity, and convenience to clinicians (slides can be mailed), this technique has replaced darkfield microscopy in some health departments and medical center laboratories.

2. Serologic tests for syphilis—(Table 34–2.) There are two general categories of serologic tests for syphilis: (1) Nontreponemal tests detect antibodies to lipoidal antigens present in the host after modification by T. pallidum. (2) Treponemal tests use live or killed T. pallidum as antigen to detect antibodies specific for pathogenic treponemes.

A. Nontreponemal antigen tests—The most commonly used nontreponemal antigen tests are the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests, which measure the ability of heated serum to flocculate a suspension of cardiolipin–cholesterol–lecithin. The flocculation tests are inexpensive, rapid, and easy to perform and have therefore been commonly used for routine screening. A different, enzyme immunoassay (EIA)-based screening algorithm has been recently introduced and is discussed below. Quantitative expression of the reactivity of the serum, based on titration of dilutions of serum, is valuable in establishing the diagnosis and in evaluating the efficacy of treatment, since titers usually correlate with disease activity.

Nontreponemal tests generally become positive 4–6 weeks after infection or 1–3 weeks after the appearance of a primary lesion; they are almost invariably positive in the secondary stage, with titers ≥ 1:16. In the late stages, titers tend to be lower (<1:4). These serologic tests are not highly specific and must be closely correlated with other clinical and laboratory findings. The tests are positive in patients with non–sexually transmitted treponematoses (see below). More important, false-positive serologic reactions are frequently encountered in a wide variety of other conditions, including connective tissue diseases, infectious mononucleosis, malaria, febrile diseases, leprosy, injection drug use, infective endocarditis, old age, hepatitis C viral infection, and pregnancy. False-positive reactions are usually of low titer and transient and may be distinguished from true positives by treponemal-specific antibody tests. False-negative results can be seen when very high antibody titers are present (the prozone phenomenon). If syphilis is strongly suspected and the nontreponemal test is negative, the laboratory should be instructed to dilute the specimen to detect a positive reaction. The RPR and VDRL tests are equally reliable, but titers of RPR tend to be higher than the VDRL. Thus, when these tests are used to follow disease activity, the same testing method should be used and preferably should be performed at the same laboratory.

Nontreponemal antibody titers are used to assess adequacy of therapy. The time required for the VDRL or RPR to become negative depends on the stage of the disease, the level of the initial titer, and whether the infection is an initial or repeat episode. In general, persons with repeat infections, higher initial titers, more advanced stages of disease, or those who are HIV positive at the time of treatment have a slower seroconversion rate and are more likely to remain serofast (ie, titers do not become negative). Data based on currently recommended treatment regimens (see below) suggest that in primary and secondary syphilis it may take 6–12 months to see a fourfold decrease in titer.

B. Treponemal antibody tests—These tests measure antibodies capable of reacting with T. pallidum antigens. The T. pallidum hemagglutination (TPHA) test and the T. pallidum particle agglutination (TPPA) test are comparable in specificity and sensitivity to the fluorescent treponemal antibody absorption test (FTA-ABS). The TPPA test, because of ease of performance, has supplanted the FTA-ABS test as the means of confirming the diagnosis of syphilis.

The treponemal tests are of value principally in determining whether a positive nontreponemal antigen test is a false-positive result (see above) or is indicative of syphilis. Because of their great sensitivity, particularly in the late stages of the disease, these tests are also of value when there is clinical evidence of syphilis but the nontreponemal serologic test for syphilis is negative. Treponemal tests are reactive in most patients with primary syphilis and in almost all patients with secondary syphilis. Although a reactive treponemal serologic test remains the same throughout a patient’s life in most cases, the treponemal-specific antibody test (like nontreponemal antibody tests) may revert to negative with adequate therapy. Final decisions about the significance of the results of serologic tests for syphilis must be based on a total clinical appraisal.
SPIROCHETAL INFECTIONS

C. EIA- or CIA-based screening algorithms—Newer screening algorithms reverse the traditional test order and begin with an automated treponemal antibody test, the EIA or CIA (chemiluminescence assay), and then follow up with a nontreponemal test (RPR or VDRL) if the treponemal test is positive. This algorithm is faster and decreases costs to laboratories when compared with traditional screening. Compared with traditional treponemal-specific tests, the EIAs have sensitivities of 95–99% and specificities of 100%.

The EIA- or CIA-based algorithms can cause challenges in clinical management. A positive EIA with a negative RPR or VDRL should be evaluated with a second treponemal test, but interpretation of discordant results is not yet fully standardized and a clinician may benefit from an expert opinion.

D. Rapid treponemal tests—A single rapid treponemal test was approved by the FDA in 2011 for use in the United States, but is not yet in widespread use. However, such rapid treponemal tests are commonly used worldwide, particularly in limited-resource settings.

3. Polymerase chain reaction—Polymerase chain reaction (PCR) has been increasingly evaluated and utilized worldwide for the diagnosis of genital ulcer disease, including syphilis, but these tests are not yet commercially available in the United States.

4. Cerebrospinal fluid examination—See Neurosyphilis section.

Diff. Diagn.

The syphilitic chancre may be confused with genital herpes, chancroid (usually painful and uncommon in the United States), lymphogranuloma venereum (also uncommon), or neoplasm. Any genital ulcer should be considered a possible primary syphilitic lesion. Simultaneous evaluation for herpes simplex virus types 1 and 2 using PCR or culture should also be done in these cases.

Prevent & Screen

Avoidance of sexual contact is the only completely reliable method of prevention but is an impractical public health measure. Latex or polyurethane condoms are effective but protect covered areas only. Screening every 6–12 months for syphilis among MSM has been recommended based on preliminary data suggesting that this may decrease the rate of transmission. High-risk individuals (those who have multiple encounters with anonymous partners or who have sex in conjunction with the use of drugs) should be screened every 3–6 months. Pregnant women should be screened at the first prenatal visit and again in the third trimester if there is a high risk of infection. Indicators of high risk include poverty, sex work, illicit drug use, history of other sexually transmitted diseases, and living in communities with high syphilis morbidity. Patients treated for other sexually transmitted diseases should also be tested for syphilis, and persons who have known or suspected contact with patients who have syphilis should be evaluated and treated to abort development of infectious syphilis (see Treating Syphilis Contacts below).

Treatment

A. Antibiotic Therapy

Penicillin remains the preferred treatment for syphilis, since there have been no documented cases of penicillin-resistant T pallidum (Table 34–3). Although doxycycline is an alternative for some patients, pregnant women must be treated with penicillin (see below).

There are limited data for ceftriaxone, although optimum dose and duration are not well defined. Azithromycin is no longer recommended in many areas due to demonstrated resistance. Patients treated for neurosyphilis should receive at least one dose of long-acting (benzathine) penicillin at the completion of therapy. All patients treated with a non-penicillin regimen must have close clinical and serologic follow up, as noted below.

B. Managing Jarisch–Hemxheimer Reaction

The Jarisch–Hemxheimer reaction, manifested by fever and aggravation of the existing clinical picture in the hours following treatment, is ascribed to the sudden massive destruction of spirochetes and is not IgE-mediated. It is most common in early syphilis, particularly secondary syphilis where it can occur in 66% of cases. The reaction resolves spontaneously within 24 hours; treatment should not be avoided, but in cases of syphilitic laryngitis, auditory neuritis or labyrinthitis, or involvement of the coronary ostia, patients must be monitored closely for morbidity associated with the reaction. It may also prompt preterm labor in pregnant women as these patients should either be admitted for treatment if they are at high risk for preterm labor, or closely observed with a plan for emergent care if needed.

The reaction may be blunted by simultaneous administration of antipyretics, although no proved method of prevention exists. In cases with increased risk of morbidity due to the Jarisch–Hemxheimer reaction, consultation with an infectious disease expert is recommended. Patients should be reminded that the reaction does not signify an allergy to penicillin.

C. Local Measures (Mucocutaneous Lesions)

Local treatment is usually not necessary. No local antiseptics or other chemicals should be applied to a suspected syphilitic lesion until specimens for microscopy have been obtained.

D. Public Health Measures

Patients with infectious syphilis must abstain from sexual activity for 7–10 days after treatment. All cases of syphilis must be reported to the appropriate local public health agency for assistance in identifying and treating sexual contacts. In addition, all patients with syphilis should have an HIV test at the time of diagnosis. In areas of high
primary and secondary syphilis, failure of nontreponemal antibody titers to decrease fourfold by 6 months may identify a group at high risk for treatment failure. Optimal management of these patients is unclear, but at a minimum, close clinical and serologic follow-up is indicated. If titers fail to decrease fourfold by 6–12 months, an HIV test should be repeated (all patients with syphilis should have an HIV test at the time of diagnosis); a lumbar puncture should be considered since unrecognized neurosyphilis can be a cause of treatment failure; and, if careful follow-up cannot be ensured (3-month intervals for HIV-positive individuals and 6-month intervals for HIV-negative patients), treatment should be repeated with 2.4 million units of benzathine penicillin intramuscularly weekly for 3 weeks. If symptoms or signs persist or recur after initial therapy or there is a fourfold or greater increase in nontreponemal titers, therapy has either failed or the patient has been reinfected. In those individuals, an HIV test should be performed, a lumbar puncture done (unless reinfection is a certainty), and re-treatment given as indicated above.

HIV prevalence, a repeat HIV test should be performed in 3 months if the initial test result was negative.

**E. Treating Syphilis Contacts**

Patients who have been sexually exposed to infectious syphilis within the preceding 3 months may be infected but seronegative and thus should be treated as for early syphilis even if serologic tests are negative. Persons exposed more than 3 months previously should be treated based on serologic results. If their partners are unavailable for testing or the patient is unreliable for follow-up, empiric therapy is indicated.

**Follow-Up Care**

Because treatment failures and reinfection may occur, patients treated for syphilis should be monitored clinically and serologically at 6 and 12 months. Response to therapy may be difficult to assess, and no definite criteria exist for cure in patients with primary or secondary syphilis. In
2. Secondary Syphilis

**ESSENTIALS OF DIAGNOSIS**
- Generalized maculopapular skin rash.
- Mucous membrane lesions, including patches and ulcers.
- Weeping papules (condyloma lata) in moist skin areas.
- Generalized nontender lymphadenopathy.
- Fever may be present.
- Meningitis, hepatitis, osteitis, arthritis, iritis may be present.
- Many treponemes in moist lesions by immunofluorescence or darkfield microscopy.
- Serologic tests for syphilis positive.

**Clinical Findings**

The secondary stage of syphilis usually appears a few weeks (or up to 6 months) after development of the chancre, when dissemination of *T pallidum* produces systemic signs (fever, lymphadenopathy) or infectious lesions at sites distant from the site of inoculation. The most common manifestations are skin and mucosal lesions. The skin lesions are nonpruritic, macular, papular, pustular, or follicular (or combinations of any of these types, but generally not vesicular). The skin lesions usually are generalized; involvement of the palms and soles (Figure 34–2) occurs in 80% of cases. Annular lesions simulating ringworm may be observed in dark-skinned individuals. Mucous membrane lesions may include mucous patches (Figure 34–3), which can be found on the lips, mouth, throat, genitalia, and anus. Specific lesions—condylomata lata (Figure 34–4)—are fused, weeping papules on the moist areas of the skin and mucous membranes and are sometimes mistaken for genital warts. The mucous membrane lesions are highly infectious.

Meningeal (aseptic meningitis or acute basilar meningitis), hepatic, renal, bone, and joint invasion may occur, with resulting cranial nerve palsies, jaundice, nephrotic syndrome, and periostitis. Alopecia (moth-eaten appearance) and uveitis may also occur.

The serologic tests for syphilis are positive in almost all cases (see Primary Syphilis). The moist cutaneous and mucous membrane lesions often show *T pallidum* on darkfield microscopic examination. A transient cerebrospinal fluid (CSF) pleocytosis is seen in 30–70% of patients with secondary syphilis, though only 5% have positive serologic CSF reactions. There may be evidence of hepatitis or nephritis (immune complex type) as circulating immune complexes are deposited in blood vessel walls.

Skin lesions may be confused with the infectious exanthems, pityriasis rosea, and drug eruptions (Figure 34–5). Visceral lesions may suggest nephritis or hepatitis due to other causes. The diffusely red throat may mimic other forms of pharyngitis.
latent syphilis is defined as the first year after primary infection and may relapse to secondary syphilis if undiagnosed or inadequately treated (see above). Relapse is almost always accompanied by a rising titer in quantitative serologic tests; indeed, a rising titer may be the first or only evidence of relapse. About 90% of relapses occur during the first year after infection.

Early latent infection can be diagnosed if there was documented seroconversion or a fourfold increase in non-treponemal titers in the past 12 months; the patient can recall symptoms of primary or secondary syphilis; or the patient had a sex partner with documented primary, secondary, or early latent syphilis.

After the first year of latent syphilis, the patient is said to be in the late latent (“hidden”) phase and noninfectious to sex partners. Transmission to the fetus, however, can probably occur in any phase. There are (by definition) no clinical manifestations during the latent phase, and the only significant laboratory findings are positive serologic tests. A diagnosis of latent syphilis is justified only when the history and physical examination show no evidence of tertiary disease or neurosyphilis. The latent phase may last from months to a lifetime.

### Treatment

Treatment of early latent syphilis and follow up is as for primary syphilis unless central nervous system or ocular disease is present, in which case treatment for neurosyphilis given (Table 34–3). See Primary Syphilis for follow-up care and treatment of contacts.

### General Considerations

Latent syphilis is the clinically quiescent phase during the interval after the disappearance of secondary lesions. Early latent syphilis: infection < 1 year in duration. Late latent syphilis: infection > 1 year in duration. No physical signs. History of syphilis with inadequate treatment. Positive serologic tests for syphilis.

4. Late (Tertiary) Syphilis

- Infiltrative tumors of skin, bones, liver (gummas).
- Aortitis, aneurysms, aortic regurgitation.
- Central nervous system disorders, including meningo-vascular and degenerative changes, paresthesias, shooting pains, abnormal reflexes, dementia, or psychosis.

### General Considerations

This stage may occur at any time after secondary syphilis, even after years of latency, and is rarely seen in developed countries in the modern antibiotic era. Late lesions are
thought to represent a delayed hypersensitivity reaction of the tissue to the organism and are usually divided into two types: (1) a localized gummatous reaction, with a relatively rapid onset and generally prompt response to therapy (“benign late syphilis”) and (2) diffuse inflammation of a more insidious onset that characteristically involves the central nervous system and large arteries, is often fatal if untreated, and is at best arrested by treatment. Gummas may involve any area or organ of the body but most often affect the skin or long bones. Cardiovascular disease is usually manifested by aortic aneurysm, aortic regurgitation, or aortitis. Various forms of diffuse or localized central nervous system involvement may occur.

Late syphilis must be differentiated from neoplasms of the skin, liver, lung, stomach, or brain; other forms of meningitis; and primary neurologic lesions.

Although almost any tissue and organ may be involved in late syphilis, the following are the most common types of involvement: skin, mucous membranes, skeletal system, eyes, respiratory system, gastrointestinal system, cardiovascular system, and nervous system.

Clinical Findings

A. Symptoms and Signs

1. Skin—Cutaneous lesions of late syphilis are of two varieties: (1) multiple nodular lesions that eventually ulcerate (lues maligna) or resolve by forming atrophic, pigmented scars and (2) solitary gummas that start as painless subcutaneous nodules, then enlarge, attach to the overlying skin, and eventually ulcerate (Figure 34–6).

2. Mucous membranes—Late lesions of the mucous membranes are nodular gummas or leukoplakia, highly destructive to the involved tissue.

3. Skeletal system—Bone lesions are destructive, causing periostitis, osteitis, and arthritis with little or no associated redness or swelling but often marked myalgia and myositis of the neighboring muscles. The pain is especially severe at night.

4. Eyes—Late ocular lesions are gummatous iritis, chorioretinitis, optic atrophy, and cranial nerve palsies, in addition to the lesions of central nervous system syphilis.

5. Respiratory system—Respiratory involvement by late syphilis is caused by gummatous infiltrates into the larynx, trachea, and pulmonary parenchyma, producing discrete pulmonary densities. There may be hoarseness, respiratory distress, and wheezing secondary to the gummatous lesion itself or to subsequent stenosis occurring with healing.

6. Gastrointestinal system—Gummas involving the liver produce the usually benign, asymptomatic hepar lobatum. A picture resembling Laennec cirrhosis is occasionally produced by liver involvement. Gastric involvement can consist of diffuse infiltration into the stomach wall or focal lesions that endoscopically and microscopically can be confused with lymphoma or carcinoma. Epigastric pain, early satiety, regurgitation, belching, and weight loss are common symptoms.

7. Cardiovascular system—Cardiovascular lesions (10–15% of late syphilitic lesions) are often progressive, disabling, and life-threatening. Central nervous system lesions are often present concomitantly. Involvement usually starts as an arteritis in the supracardiac portion of the aorta and progresses to one or more of the following: (1) narrowing of the coronary ostia, with resulting decreased coronary circulation, angina, and acute myocardial infarction; (2) scarring of the aortic valves, producing aortic regurgitation, and eventually congestive heart failure; and (3) weakness of the wall of the aorta, with saccular aneurysm formation (Figure 34–7) and associated pressure symptoms of dysphagia, hoarseness, brassy cough, back pain (vertebral erosion), and occasionally rupture of the aneurysm. Recurrent respiratory infections are common as a result of pressure on the trachea and bronchi.

8. Nervous system (neurosyphilis)—See following section.
3. **Tabes dorsalis**—This form is a chronic progressive degeneration of the parenchyma of the posterior columns of the spinal cord and of the posterior sensory ganglia and nerve roots. The symptoms and signs are impairment of proprioception and vibration sense, Argyll Robertson pupils (which react poorly to light but well to accommodation), and muscular hypotonia and hyporeflexia. Impairment of proprioception results in a wide-based gait and inability to walk in the dark. Paresthesias, analgesia, or sharp recurrent pains in the muscles of the leg (“shooting” or “lightning” pains) may occur. Crises are also common in tabes: gastric crises, consisting of sharp abdominal pains with nausea and vomiting (simulating an acute abdomen); laryngeal crises, with paroxysmal cough and dyspnea; urethral crises, with painful bladder spasms; and rectal and anal crises. Crises may begin suddenly, last for hours to days, and cease abruptly. Neurogenic bladder with overflow incontinence is also seen. Painless trophic ulcers may develop over pressure points on the feet. Joint damage may occur as a result of lack of sensory innervation (Charcot joint, Figure 34–8). The CSF may have a normal or increased cell count, elevated protein, and variable results of serologic tests.

4. **General paresis**—This is generalized involvement of the cerebral cortex with insidious onset of symptoms. There is usually a decrease in concentrating power, memory loss, dysarthria, tremor of the fingers and lips, irritability, and mild headaches. Most striking is the change of personality; the patient may become slovenly, irresponsible, confused, and psychotic. The CSF findings resemble those of tabes dorsalis. Combinations of the various forms of neurosyphilis (especially tabes and paresis) are not uncommon.

### B. Laboratory Findings

**1. Indications for a lumbar puncture**—In early syphilis (primary and secondary syphilis and early latent syphilis of < 1 year duration), invasion of the central nervous system can occur at any stage of disease. Consider both clinical presentation and laboratory data. Carefully evaluate HIV-positive patients and consider CSF evaluation for atypical symptoms or lack of decrease in nontreponemal serology titers.

### General Considerations

Neurosyphilis can occur at any stage of disease and can be a progressive, disabling, and life-threatening complication. CSF pleocytosis has been reported in 10–20% of patients with primary syphilis. Asymptomatic and meningo-vascular syphilis occur earlier (months to years after infection, sometimes coexisting with primary and secondary syphilis) than tabes dorsalis and general paresis (2–50 years after infection).

### Clinical Findings

#### A. Classification

1. **Asymptomatic neuroinvasion**—This form is characterized by spinal fluid abnormalities (positive spinal fluid serology, increased cell count, occasionally increased protein) without symptoms or signs of neurologic involvement. There are no clear data to support that these asymptomatic CSF abnormalities have clinical significance.

2. **Meningovascular syphilis**—This form is characterized by meningeal involvement or changes in the vascular structures of the brain (or both), producing symptoms of acute or chronic meningitis (headache, irritability); cranial nerve palsies (basilar meningitis); unequal reflexes; irregular pupils with poor light and accommodation reflexes; and when large vessels are involved, cerebrovascular accidents. The CSF shows increased cells (100–1000/mcL), elevated protein, and may have a positive serologic test (CSF VDRL) for syphilis. The symptoms of acute meningitis are rare in late syphilis.

#### Figure 34–8. Neuropathic arthropathy (Charcot joint) from tertiary syphilis. (Courtesy of Susan Lindsley, Public Health Image Library, CDC.)
by *T. pallidum* with CSF abnormalities occurs commonly, but clinical neurosyphilis rarely develops in patients who have received the standard therapy outlined above. Thus, unless clinical symptoms and signs of neurosyphilis or ophthalmologic involvement (uveitis, neuroretinitis, optic neuritis, iritis) are present, a lumbar puncture in early syphilis is not recommended as part of the routine evaluation. In latent syphilis, routine lumbar puncture is not indicated since the yield is low and findings rarely influence therapeutic decisions. CSF evaluation is recommended, however, if neurologic or ophthalmologic symptoms and signs are present, if there is evidence of treatment failure (see earlier discussion), or if there is evidence of active tertiary syphilis (eg, aortitis, iritis, optic atrophy, the presence of a gumma).

2. **Spinal fluid examination**—CSF findings in neurosyphilis are variable. In “classic” cases, there is an elevation of total protein, lymphocytic pleocytosis, and a positive CSF reagin test (VDRL). The serum nontreponemal titers will be reactive in most cases. In later stages of syphilis, normal CSF analysis in the presence of infection can occur, but it is unusual. False-positive reagin tests rarely occur in the CSF; a positive test confirms the presence of neurosyphilis. Because the CSF VDRL may be negative in 30–70% of cases of neurosyphilis, a negative test does not exclude neurosyphilis. The CSF FTA-ABS is sometimes used; it is a highly sensitive test but lacks specificity, and a high serum titer of FTA-ABS may result in a positive CSF titer in the absence of neurosyphilis.

### Treatment

Current recommendations for the therapy of neurosyphilis include high doses of aqueous penicillin to achieve better penetration and higher levels of drug in the CSF than is possible with benzathine penicillin (Table 34–3). Because of concerns about slowly dividing organisms that may persist after only 10–14 days of therapy, many experts recommend subsequent administration of 2.4 million units of the longer-acting benzathine penicillin intramuscularly once weekly for up to 3 weeks as additional therapy. There are some data for using ceftriaxone to treat neurosyphilis as well, but because this and other regimens have not been adequately studied, patients with a history of an IgE-mediated reaction to penicillin should be skin tested for allergy to penicillin and, if positive, desensitized.

All patients treated for neurosyphilis should have nontreponemal serologic tests done every 3–6 months. Guidelines established by the Centers for Disease Control and Prevention (CDC) recommend spinal fluid examinations at 6-month intervals until the CSF cell count is normal; however, there are data to suggest that in certain patients normalization of serum titers is an acceptable surrogate for CSF response. In general, CSF white blood cell count and CSF VDRL normalize more quickly (usually in 12 months) than CSF protein concentration, which can remain abnormal for extended periods. If the serum nontreponemal titers do not normalize, the CSF analysis should be repeated. A second course of penicillin therapy may be given if the CSF cell count has not decreased at 6 months or is not normal at 2 years.

### 6. Syphilis in HIV-Infected Patients

Syphilis is common among HIV-infected individuals. Some data suggest that syphilis coinfection is associated with an increase in HIV viral load and a decrease in CD4 count that normalizes with therapy. Researchers from a prospective cohort study of HIV-infected individuals reported that they found no association with HIV disease progression in persons with syphilis coinfection. However, for optimal patient care as well as prevention of transmission to partners, guidelines for the primary care of HIV-infected patients recommend routine syphilis screening.

Interpretation of serologic tests should be the same for HIV-positive and HIV-negative persons. Although unusual serologic responses have been reported in HIV-positive patients, including high titers of nontreponemal tests, delayed appearance of positive titers, and false-negative tests, most HIV-positive patients respond serologically in largely the same way as noninfected patients. All HIV-positive patients in care should be screened at least twice a year to identify latent disease because by establishing a serologic history, unnecessary lumbar punctures and prolonged treatment for latent syphilis of uncertain duration can be avoided. If the diagnosis of syphilis is suggested on clinical grounds but reagin tests are negative, alternative tests should be performed. These tests include darkfield examination of lesions and direct fluorescent antibody staining for *T. pallidum* of lesion exudate or biopsy specimens.

Treatment of HIV-positive patients with primary and secondary syphilis is the same as for HIV-negative patients, with careful clinical and serologic follow-up at 3, 6, 9, 12, and 24 months. HIV-infected patients with late latent syphilis, syphilis of uncertain duration, and neurosyphilis should be treated like HIV-negative individuals, with follow-up at 6, 12, 18, and 24 months. A study among HIV-clinic patients in Baltimore found that the use of antiretroviral therapy was associated with reduced serologic failure rates after syphilis treatment.

The diagnosis of neurosyphilis in HIV-infected patients is complicated by the fact that CSF abnormalities are frequently seen if lumbar puncture is performed. The significance of these abnormalities is unknown, and similar abnormalities are frequently seen in non–HIV-infected patients with primary or secondary syphilis. Thus, CSF testing is not recommended in those with early disease and a normal neurologic examination. In contrast, a lumbar puncture should be performed in all patients, regardless of HIV-infection status, if neurologic signs are present or if therapy has failed. Following treatment, CSF white blood cell counts normalize within 12 months regardless of HIV status, while the CSF VDRL is slower to normalize in HIV-infected individuals, especially those with CD4 counts < 200 cells/mcL. As discussed above, the same criteria for failure apply to HIV-positive and HIV-negative patients, and re-treatment regimens are the same.

Because clinical experience in treating HIV-infected patients with syphilis is based on penicillin regimens, few options exist for treating the penicillin-allergic patient. Doxycycline or tetracycline regimens can be used for primary, secondary, and early latent syphilis as well as for late
latent syphilis and latent syphilis of unknown duration though with caution and close follow-up (Table 34–3). For neurosyphilis, penicillin regimens are optimal even if this requires skin testing and desensitization; limited data exist for ceftriaxone.

7. Syphilis in Pregnancy

All pregnant women should have a nontreponemal serologic test for syphilis at the time of the first prenatal visit (see Chapter 19). In women who may be at increased risk for syphilis or for populations in which there is a high prevalence of syphilis, additional nontreponemal tests should be performed during the third trimester at 28 weeks and again at delivery. The serologic status of all women who have delivered should be known before discharge from the hospital. Seropositive women should be considered infected and should be treated unless prior treatment with fall in antibody titer is medically documented.

The only acceptable treatment for syphilis in pregnancy is penicillin in dosage schedules appropriate for the stage of disease (see above). Penicillin prevents congenital syphilis in 90% of cases, even when treatment is given late in pregnancy. Tetracycline and doxycycline are contraindicated in pregnancy. Erythromycin should not be used because of failure to eradicate infection in the fetus, and insufficient data are available to justify a recommendation for ceftriaxone or azithromycin. Thus, women with a history of penicillin allergy should be skin tested and desensitized if necessary.

The infant should be evaluated immediately, as noted below, and at 6–8 weeks of age.

8. Congenital Syphilis

Congenital syphilis is a transplacentally transmitted infection that occurs in infants of untreated or inadequately treated mothers. The physical findings at birth are quite variable: The infant may have many or minimal signs or even no signs until 6–8 weeks of life (delayed form). The most common findings are on the mucous membranes and skin—maculopapular rash, condylomas, mucous membrane patches, and serous nasal discharge (snuffles). These lesions are infectious; T pallidum can easily be found microscopically, and the infant must be isolated. Other common findings are hepatosplenomegaly, anemia, or osteochondritis. These early active lesions subsequently heal, but if the disease is left untreated it produces the characteristic stigmas of congenital syphilis—interstitial keratitis, Hutchinson teeth, saddle nose, saber shins, deafness, and central nervous system involvement.

The presence of negative serologic tests at birth in both the mother and the infant usually means that the newborn is free of infection. However, recent infection near the time of delivery may result in negative tests because there has been insufficient time to develop a serologic response. Thus, it is necessary to maintain a high index of suspicion in infants born to high-risk mothers (eg, HIV-positive, illicit drug users). All infants born to mothers with positive nontreponemal and treponemal antibody titers should have blood drawn for an RPR or VDRL test and, if positive, be referred to a pediatrician for further evaluation and therapy.

When to Refer

- Consultation with the local public health department may help obtain all prior positive syphilis serologic results and may be helpful in complicated or atypical cases.
- Early (infectious) syphilis cases may be contacted for partner notification and treatment by local public health authorities.

When to Admit

- Pregnant women with syphilis and true penicillin allergy should be admitted for desensitization and treatment.
- Women in late pregnancy treated for early syphilis should have close outpatient monitoring or be admitted because the Jarisch-Herxheimer reaction can induce premature labor.
- Patients with neurosyphilis usually require admission for treatment with aqueous penicillin.

NON–SEXUALLY TRANSMITTED TREPONEMATOSES

A variety of treponemal diseases other than syphilis occur endemically in many tropical areas of the world. They are distinguished from disease caused by T pallidum by their nonsexual transmission, their relatively high incidence in certain geographic areas and among children, and their tendency to produce less severe visceral manifestations. As in syphilis, organisms can be demonstrated in infectious lesions with darkfield microscopy or immunofluorescence but cannot be cultured in artificial media; the serologic tests for syphilis are positive; the diseases have primary, secondary, and sometimes tertiary stages; and penicillin is the drug of choice. There is evidence that infection with these agents may provide partial resistance to syphilis and vice versa. Treatment with penicillin in doses appropriate to primary syphilis (eg, 2.4 million units of benzathine penicillin G intramuscularly) is generally curative in any stage of the non–sexually transmitted treponematoses. In cases of penicillin hypersensitivity, tetracycline, 500 mg orally four times a day for 10–14 days, is usually the recommended alternative.
**YAWS (Frambesia)**

Yaws is a contagious disease largely limited to tropical regions that is caused by *T. pallidum* subspecies *pertenue*. It is characterized by granulomatous lesions of the skin, mucous membranes, and bone. Yaws is rarely fatal, though if untreated it may lead to chronic disability and disfigurement. Yaws is acquired by direct nonsexual contact, usually in childhood, although it may occur at any age. The “mother yaw,” a painless papule that later ulcerates, appears 3–4 weeks after exposure. There is usually associated regional lymphadenopathy. Six to 12 weeks later, secondary lesions that are raised papillomas and papules that weep highly infectious material appear and last for several months or years. Painful ulcerated lesions on the soles are called “crab yaws” because of the resulting gait. Late gummatous lesions may occur, with associated tissue destruction involving large areas of skin and subcutaneous tissues. The late effects of yaws, with bone change, shortening of digits, and contractions, may be confused with similar changes occurring in leprosy. Central nervous system, cardiac, or other visceral involvement is rare. See above for therapy.

**PINTA**

Pinta is a non–sexually transmitted spirochetal infection caused by *T. pallidum* subspecies *carateum*. It occurs endemically in rural areas of Latin America, especially in Mexico, Colombia, and Cuba, and in some areas of the Pacific. A nonulcerative, erythematous primary papule spreads slowly into a papulosquamous plaque showing a variety of color changes (slate, lilac, black). Secondary lesions resemble the primary one and appear within a year after it. These appear successively, new lesions together with older ones; are most common on the extremities; and later show atrophy and depigmentation. Some cases show pigmentedary changes and atrophic patches on the soles and palms, with or without hyperkeratosis, that are indistinguishable from “crab yaws.” Very rarely, central nervous system or cardiovascular disease is observed late in the course of infection. See above for therapy.

**ENDEMIC SYPHILIS**

Endemic syphilis is an acute or chronic infection caused by *T. pallidum* subspecies *endemicum*. It has been reported in a number of countries, particularly in the eastern Mediterranean area, often with local names: bejel in Syria, Saudi Arabia, and Iraq, and dichuchwa, njovera, and siti in Africa. It also occurs in Southeast Asia. The local forms have distinctive features. Moist ulcerated lesions of the skin or oral or nasopharyngeal mucosa are the most common manifestations. Generalized lymphadenopathy and secondary and tertiary bone and skin lesions are also common. Deep leg pain points to periostitis or osteomyelitis. In the late stages of disease, destructive gummatous lesions similar to those seen in yaws can develop, resulting in loss of cartilage and saber shin deformity. Cardiovascular and central nervous system involvement are rare. See above for therapy.
false-positive indirect fluorescent antibody and Western blot tests for Borrelia burgdorferi, and some cases may be misdiagnosed as Lyme disease. PCR assays have been developed but are not widely available. CSF abnormalities occur in patients with meningeal involvement. Mild anemia and thrombocytopenia are common, but the white blood cell count tends to be normal.

**Differential Diagnosis**

The manifestations of relapsing fever may be confused with malaria, leptospirosis, meningococcemia, yellow fever, typhus, or rat-bite fever.

**Prevention**

Prevention of tick bites (as described for rickettsial diseases) and delousing procedures applicable to large groups can prevent illness. Arthropod vectors should be controlled if possible.

Postexposure prophylaxis with doxycycline 200 mg orally on day 1 and 100 mg daily for 4 days has been shown to prevent recurrent fever following tick bites in highly endemic areas.

**Treatment**

A single dose of tetracycline or erythromycin, 0.5 g orally, or a single dose of procaine penicillin G, 600,000–800,000 units intramuscularly (adults) or 400,000 units intramuscularly (children), probably constitutes adequate treatment for louse-borne relapsing fevers; however, some experts advocate for longer courses of treatment to prevent persistent infection. Because of higher relapse rates, tick-borne disease is routinely treated with 0.5 g of tetracycline or erythromycin given orally four times daily for 10 days. If central nervous system invasion is suspected, penicillin G, 3 million units intravenously every 4 hours, or ceftriaxone, 1 g intravenously daily, should be given for 10-14 days. Jarisch–Herxheimer reactions occur commonly following treatment and may be life-threatening, so patients should be closely monitored (see Syphilis, above). One study in patients with louse-borne relapsing fever showed that administration of anti-TNF antibodies prior to antibiotic therapy can be effective in preventing the reaction.

**Prognosis**

The overall mortality rate is usually about 5%. Fatalities are most common in old, debilitated, or very young patients. With treatment, the initial attack is shortened and relapses are largely prevented.

**Rat-Bite Fever**

Rat-bite fever is an uncommon acute infectious disease caused by the treponeme Spirillum minus (Asia), covered in this section, or the bacteria Streptobacillus moniliformis (North America). It is transmitted to humans by the bite of a rat. Inhabitants of rat-infested dwellings and laboratory workers are at greatest risk.

**Clinical Findings**

**A. Symptoms and Signs**

In *Spirillum* infections, the original rat bite, unless secondarily infected, heals promptly, but 1 to several weeks later the site becomes swollen, indurated, and painful; assumes a dusky purplish hue; and may ulcerate. Regional lymphangitis and lymphadenitis, fever, chills, malaise, myalgia, arthralgia, and headache are present. Splenomegaly may occur. A sparse, dusky-red maculopapular rash appears on the trunk and extremities in many cases, and there may be frank arthritis.

After a few days, both the local and systemic symptoms subside, only to reappear several days later. This relapsing pattern of fever for 3–4 days alternating with afebrile periods lasting 3–9 days may persist for weeks. The other features, however, usually recur only during the first few relapses. Endocarditis is a rare complication of infection.

**B. Laboratory Findings**

Leukocytosis is often present, and the nontreponemal test for syphilis is often falsely positive. The organism may be identified in darkfield examination of the ulcer exudate or aspirated lymph node material; more commonly, it is observed after inoculation of a laboratory animal with the patient’s exudate or blood. It has not been cultured in artificial media.

**Differential Diagnosis**

Rat-bite fever must be distinguished from the rat-bite–induced lymphadenitis and rash of streptobacillary fever. Clinically, the severe arthritis and myalgias seen in streptobacillary disease are rarely seen in disease caused by *S minus*. Reliable differentiation requires an increasing titer of agglutinins against *S moniliformis* or isolation of the causative organism. Other diseases in the differential include tularemia, rickettsial disease, Pasteurella multocida infections, and relapsing fever.

**Treatment**

Penicillin is given for 10–14 days. During the acute phase of illness, the intravenous route is used (1–2 million units every 4–6 hours) and once improvement has occurred, therapy is completed with oral medication, penicillin V 300 mg four times daily to complete 10–14 days of therapy. For the penicillin-allergic patient, tetracycline 500 mg orally four times daily or doxycycline 100 mg twice a day can be used.
A rare but severe manifestation is hemorrhagic pneumonia. The illness is usually self-limited, lasting 4–30 days, and complete recovery is the rule.

Icteric leptospirosis (Weil syndrome) is the most severe form of the disease, characterized by impaired kidney and liver function, abnormal mental status, hemorrhagic pneumonia, hypotension, and a 5–40% mortality rate. Symptoms and signs often are continuous and not biphasic.

Leptospirosis with jaundice must be distinguished from hepatitis, yellow fever, and relapsing fever.

B. Laboratory Findings

The leukocyte count may be normal or as high as 50,000/mcL (0.05/L), with neutrophils predominating. The urine may contain bile, protein, casts, and red cells. Oliguria is common, and in severe cases uremia may occur. Elevated bilirubin and aminotransferases are seen in 75%, and elevated creatinine (>1.5 mg/dL) (>132.6 mcMol/L) is seen in 50% of cases. In cases with meningeal involvement, organisms may be found in the CSF during the first 10 days of illness. Early in the disease, the organism may be identified by darkfield examination of the patient’s blood (a test requiring expertise since false-positives are frequent in inexperienced hands) or by culture on a semisolid medium (eg, Fletcher EMJH). Cultures take 1–6 weeks to become positive. The organism may also be grown from the urine from the tenth day to the sixth week. Diagnosis is usually made by means of serologic tests. Agglutination tests (microscopic, using live organisms, and macroscopic, using killed antigen) become positive after 7–10 days of illness, peak at 3–4 weeks, and may persist at high levels for many years. Thus, to make a diagnosis, a fourfold or greater rise in titer must be documented. The agglutination tests are cumbersome to perform and require trained personnel. Indirect hemagglutination and enzyme-linked immunosorbent assay (ELISA) tests are also available. The IgM EIA is particularly useful in making an early diagnosis, since it is positive as early as 2 days into illness, a time when the clinical manifestations may be nonspecific, and it is extremely sensitive and specific (93%). PCR methods (presently investigational) appear to be sensitive, specific, positive early in disease, and able to detect leptospiral DNA in blood, urine, CSF, and aqueous humor. Serum creatine kinase (CK) is usually elevated in persons with leptospirosis and normal in persons with hepatitis.

Compli cations

Myocarditis, aseptic meningitis, acute kidney injury, and pulmonary infiltrates with hemorrhage are not common but are the usual causes of death. Iridocyclitis may occur.

Prevention

The mainstay of prevention is avoidance of potentially contaminated food and water.

Prophylaxis with doxycycline has been effective in trials but is not routinely recommended. Human vaccine is used in some limited settings but is not available in the United States.
TREATMENT

Various antimicrobial drugs, including penicillin, ceftriaxone, and tetracyclines, show antileptospiral activity. Penicillin (eg, 1.5 million units every 6 hours intravenously) or ceftriaxone (1 g daily intravenously) is the drug of choice in severe leptospirosis and is especially effective if started within the first 4 days of illness. Jarisch–Herxheimer reactions may occur (see Syphilis, above). Doxycycline, 100 mg orally twice daily for 7 days, is also effective as therapy if started early, but this agent is most often used in mild to moderate disease. Although therapy for mild disease is controversial, most clinicians treat with oral penicillin, 500 mg four times daily, or doxycycline, 100 mg orally twice daily, for 7 days. Azithromycin is also active, but clinical experience is limited.

PROGNOSIS

Without jaundice, the disease is almost never fatal. With jaundice, the mortality rate is 5% for those under age 30 years and 40% for those over age 60 years.

WHEN TO ADMIT

Patients with jaundice or other evidence of severe disease should be admitted for close monitoring and may require admission to an intensive care unit.

LYME DISEASE (Lyme Borreliosis)

ESSENTIALS OF DIAGNOSIS

- Erythema migrans, a flat or slightly raised red lesion that expands with central clearing.
- Headache or stiff neck.
- Arthralgias, arthritis, and myalgias; arthritis is often chronic and recurrent.
- Wide geographic distribution, with most United States cases in the Northeast, mid-Atlantic, upper Midwest, and Pacific coastal regions.

GENERAL CONSIDERATIONS

This illness, named after the town of Old Lyme, Connecticut, is the most common tick-borne disease in the United States and Europe and is caused by genospecies of the spirochete B burgdorferi. In the United States, the causative genospecies is B burgdorferi sensu strictu, whereas in Europe and Asia B garinii and B afzelii predominate. Most US cases are reported from the mid-Atlantic, northeastern, and north central regions of the country. The true incidence of Lyme disease is not known for a number of reasons: (1) serologic tests are not standardized (see below); (2) clinical manifestations are nonspecific; and (3) even with reliable testing, serology is insensitive in early disease.

The vector of Lyme disease varies geographically and is Ixodes scapularis in the northeastern, north central, and mid-Atlantic regions of the United States; I pacificus on the West Coast; Ixodes r in Europe; and I persulcatus in Asia. The disease also occurs in Australia. Mice and deer make up the major animal reservoir of B burgdorferi, but other rodents and birds may also be infected. Domestic animals such as dogs, cattle, and horses can also develop clinical illness, usually manifested as arthritis.

Under experimental conditions, ticks must feed for 24–36 hours or longer to transmit infections. Most cases are reported in the spring and summer months. Human epidemiologic studies have indicated that the incidence of disease is significantly higher when tick attachment is for longer than 72 hours than if it is < 72 hours, though rare cases have been documented with attachment of < 24 hours. In addition, the percentage of ticks infected varies on a regional basis. In the northeastern and midwestern regions, 15–65% of I scapularis ticks are infected with the spirochete; in the western United States, only 2% of I pacificus are infected. These are important epidemiologic features in assessing the likelihood that tick exposure will result in disease. Exposure to I pacificus is unlikely to result in disease, since so few ticks are infected, but this is not true of exposure to I scapularis. Eliciting a history of brushing a tick off the skin (ie, the tick was not feeding) or removing a tick on the same day as exposure (ie, the tick did not feed long enough) decreases the likelihood that infection will develop.

Ixodes ticks are smaller than the more common dog ticks (Dermacentor variabilis). Larvae are < 1 mm in size, and the adult female is 2–3 mm in size, with a red body and black legs. After a blood meal, ticks can reach two to three times their unengorged size. Because the tick is so small, the bite is usually painless and goes unnoticed. After feeding, the tick drops off in 2–4 days. If a tick is found, it should be removed immediately. The best way to accomplish this is to use a fine-tipped tweezers to pull firmly and repeatedly on the tick’s mouth part—not the tick’s body—until the tick releases its hold. Saving the tick in a bottle of alcohol for future identification may be useful, especially if symptoms develop.

CLINICAL FINDINGS

Prior clinical description of Lyme disease divided the illness into three stages: stage 1, flu-like symptoms and a typical skin rash (erythema migrans, see Figure 6–28); stage 2, weeks to months later, facial (cranial nerve VII) palsy or meningitis; and stage 3, months to years later, arthritis. The problem with this simplified scheme is that there is a great deal of overlap, and the skin, central nervous system, and musculoskeletal system can be involved early or late. A more accurate classification divides disease into early and late manifestations and specifies whether disease is localized or disseminated.
A. Symptoms and Signs

1. Stage 1, early localized infection—Stage 1 infection is characterized by erythema migrans. About 1 week after the tick bite (range, 3–30 days; median 7–10 days), a flat or slightly raised red lesion appears at the site, which is commonly seen in areas of tight clothing such as the groin, thigh, or axilla. This lesion expands over several days. Although originally described as a lesion that progresses with central clearing (“bulls-eye” lesion), often there is a more homogeneous appearance or even central intensification. About 10–20% of patients either do not have typical skin lesions or the lesions go unnoticed. Most patients with erythema migrans will have a concomitant viral-like illness (the “summer flu”) characterized by myalgias, arthralgias, headache, and fatigue. Fever may or may not be present. Even without treatment, the symptoms and signs of erythema migrans resolve in 3–4 weeks. Although the classic lesion of erythema migrans is not difficult to recognize, atypical forms can occur that may lead to misdiagnosis. Vesicular, urticarial, and evanescent erythema migrans have all been reported. Similarly, chemical reactions to tick and spider bites (these usually recede in 24–48 hours whereas erythema migrans increases in size in this time period), drug eruptions, urticaria, and staphylococcal and streptococcal cellulitis have been mistaken for erythema migrans.

   Completely asymptomatic disease, without erythema migrans or flu-like symptoms, can occur but is very uncommon in the United States. Serosurveys done as part of vaccination trials found asymptomatic seroconversion in 7% or less of the population.

2. Stage 2, early disseminated infection—Up to 50–60% of patients with erythema migrans are bacteremic. Within days to weeks of the original infection, secondary skin lesions that are not associated with a tick bite develop in about 50% of patients. These lesions are similar in appearance to the primary lesion but are usually smaller. Malaise, fatigue, fever, headache (sometimes severe), neck pain, and generalized achiness are common with the skin lesions. Most symptoms are transient, although fatigue may persist for months. After hematogenous spread, the organism may sequester itself in certain areas and produce focal symptoms. Some patients experience cardiac (4–10% of patients) or neurologic (10–15% of patients) manifestations. Cardiac involvement includes myopericarditis, with atrial or ventricular arrhythmias and heart block. Neurologic manifestations include both the central and peripheral nervous systems. The most common central nervous system manifestation is an aseptic meningitis with mild headache and neck stiffness. The most common peripheral manifestation is a cranial neuropathy; i.e., facial palsy (usually unilateral but can be bilateral, see Figure 24–2). A sensory or motor radiculopathy and mononeuritis multiplex occur less frequently. Conjunctivitis, keratitis and, rarely, panophthalmitis can also occur.

3. Stage 3, late persistent infection—Stage 3 infection occurs months to years after the initial infection and again primarily manifests itself as musculoskeletal, neurologic, and skin disease. In early reports, musculoskeletal complaints developed in up to 60% of patients. With early recognition and treatment of disease, joint complaints develop in < 10% of patients. The classic manifestation of late disease is a monarticular or oligoarticular arthritis most commonly affecting the knee or other large weight bearing joints. While these joints may be quite swollen, these patients generally report less pain compared to patients with bacterial septic arthritis. Even if untreated, the arthritis is self-limited, resolving in a few weeks to months. Multiple recurrences are common but are usually less severe than the original disease. Joint fluid reflects an inflammatory arthritis with a mean white blood cell count of 25,000/mcL (0.025/L) with a predominance of neutrophils. Chronic arthritis develops in about 10% of patients. The pathogenesis of chronic Lyme arthritis may be an immunologic phenomenon rather than persistence of infection.

   Rarely, the nervous system (both central and peripheral) can be involved in late Lyme disease. In the United States, a subacute encephalopathy, characterized by memory loss, mood changes, and sleep disturbance, is seen. In Europe, a more severe encephalomyelitis caused by B. burgdorferi is seen and presents with cognitive dysfunction, spastic paraparesis, ataxia, and bladder dysfunction. Peripheral nervous system involvement includes intermit-tent paresthesias, often in a stocking glove distribution, or radicular pain.

   The cutaneous manifestation of late infection, which can occur up to 10 years after infection, is acrodermatitis chronicum atrophicans. It has been described mainly in Europe after infection with B. afzelii, a genospecies that commonly causes disease in Europe but not the United States. There is usually bluish-red discoloration of a distal extremity with associated swelling. These lesions become atrophic and sclerotic with time and eventually resemble localized scleroderma. Cases of diffuse fasciitis with eosinophilia, an entity that resembles scleroderma, have been rarely associated with infection with B. burgdorferi.

B. Laboratory Findings

The diagnosis of Lyme disease is based on both clinical manifestations and laboratory findings. The National Surveillance Case Definition specifies a person with exposure to a potential tick habitat (within the 30 days just prior to developing erythema migrans) with (1) erythema migrans diagnosed by a physician or (2) at least one late manifestation of the disease and (3) laboratory confirmation as fulfilling the criteria for Lyme disease.

   Nonspecific laboratory abnormalities can be seen, particularly in early disease. The most common are an elevated sedimentation rate of > 20 mm/h seen in 50% of cases, and mildly abnormal liver function tests are present in 30%. The abnormal liver function tests are transient and return to normal within a few weeks of treatment. A mild anemia, leukocytosis (11,000–18,000/mcL) (0.011–0.018/L), and microscopic hematuria have been reported in ≤ 10% of patients.

   Laboratory confirmation requires serologic tests to detect specific antibodies to B. burgdorferi in serum, preferably by ELISA and not by indirect immunofluorescence assay (IFA), which is less sensitive and specific and can
lead to diagnostic confusion. A two-test approach is recommended for the diagnosis of active Lyme disease, with all specimens positive or equivocal by ELISA then confirmed with an Western immunoblot assay that can detect both IgM and IgG antibodies. IgM antibody appears first 2–4 weeks after onset of erythema migrans, peaks at 6–8 weeks, and then declines to low levels after 4–6 months of illness. The presence of IgM antibody in patients with prolonged symptoms persisting for several months is likely to be a false-positive result. IgG occurs later (6–8 weeks after onset of disease), peaks at 4–6 months, and may remain elevated at low levels indefinitely despite appropriate therapy and resolution of symptoms. When an Western immunoblot is done during the first 4 weeks of illness, both IgM and IgG should be tested. A positive immunoblot requires that antibodies are detected against two (for IgM) or five (for IgG) specific protein antigens from *B. burgdorferi*.

If a patient with suspected early Lyme disease has negative serologic studies, acute and convalescent titers should be obtained since up to 50% of patients with early disease can be antibody negative in the first several weeks of illness. A fourfold rise in antibody titer would be diagnostic of recent infection. In patients with later stages of disease, almost all are antibody positive. False-positive reactions in the ELISA and IFA have been reported in juvenile rheumatoid arthritis, rheumatoid arthritis, systemic lupus erythematosus, infectious mononucleosis, subacute infective endocarditis, syphilis, relapsing fever, leptospirosis, enteroviral and other viral illnesses, and patients with gingival disease (presumably because of cross-reactivity with oral treponemes). False-negative serologic reactions occur early in illness, and antibiotic therapy early in disease can abort subsequent seroconversion.

The diagnosis of late *neuroborreliosis* is often difficult since clinical manifestations, such as subtle memory impairment, may be difficult to document. Most patients with neuroborreliosis have a history of previous erythema migrans or monarticular or polyarticular arthritis, and the vast majority have antibody present in serum. When CSF is sampled from patients with encephalopathy, there may be evidence of inflammation (pleocytosis or elevated protein, or both), and localized antibody production, ie, a ratio of CSF to serum antibody of > 1.0. The role of other tests such as PCR in detection of DNA or ELISA in detecting the presence of outer surface protein A (OspA) antigen is unclear, but in difficult cases these tests can be performed and, if positive, help establish the diagnosis. Patients with late disease and peripheral neuropathy almost always have positive serum antibody tests, usually have abnormal electrophysiology tests, and may have abnormal nerve biopsies showing perivascular collections of lymphocytes. Because disease involves peripheral nerves, the CSF is usually normal and does not demonstrate local antibody production.

Caution should be exercised in interpreting serologic tests because they are not subject to national standards, and inter-laboratory variation is a major problem. In addition, some laboratories perform tests that are entirely unreliable and should never be used to support the diagnosis of Lyme disease (eg, the Lyme urinary antigen test, immunofluorescent staining for cell wall-deficient forms of *B. burgdorferi*, lymphocyte transformation tests, using PCR on inappropriate specimens such as blood or urine). Finally, testing is often done in patients with nonspecific symptoms such as headache, arthralgia, myalgia, fatigue, and palpitations. Even in endemic areas, the pretest probability of having Lyme disease is low in these patients, and the probability of a false-positive test result is greater than that of a true-positive result. For these reasons, the American College of Physicians has established guidelines for laboratory evaluation of patients with suspected Lyme disease:

1. The diagnosis of early Lyme disease is clinical (ie, exposure in an endemic area, with physician-documented erythema migrans), and does not require laboratory confirmation. (Tests are often negative at this stage.)

2. Late disease requires objective evidence of clinical manifestations (recurrent brief attacks of monarticular or oligoarticular arthritis of the large joints; lymphocytic meningitis, cranial neuritis [facial palsy], peripheral neuropathy or, rarely, encephalomyelitis—but not headache, fatigue, paresthesias, or stiff neck alone; atrioventricular conduction defects with or without myocarditis) and laboratory evidence of disease (two-stage testing with ELISA and Western blot, as described above).

3. Patients with nonspecific symptoms without objective signs of Lyme disease should not have serologic testing done. It is in this setting that false-positive tests occur more commonly than true-positive tests.

4. The role of serologic testing in neuroborreliosis is unclear, as sensitivity and specificity of CSF serologic tests have not been determined. However, it is rare for a patient with neuroborreliosis to have positive serologic tests on CSF without positive tests on serum (see below).

5. Other tests such as the T cell proliferative assay and urinary antigen detection have not yet been studied well enough to be routinely used.

Cultures for *B. burgdorferi* can be performed but are not routine and are usually reserved for clinical studies. Aspiration of erythema migrans lesions has yielded positive cultures in up to 30% of cases, whereas culture of a 2-mm punch biopsy is positive in 50–70%. PCR of a skin biopsy is even more sensitive, with positivity rates of 80%. In early disease, blood cultures are positive in up to 50% if large volumes (9 mL) are used, but CSF is rarely culture positive. The ability to culture organisms from skin lesions is greatly influenced by antibiotic therapy. Even a brief course of several days will result in negative cultures. Special silver staining of chronically inflamed synovial tissue demonstrates spirochetes in one-third of patients.

PCR is very specific for detecting the presence of *Borrelia* DNA, but sensitivity is variable and depends on which body fluid is tested, the stage of the disease, and collection and testing technique. In general, PCR is more
sensitive than culture, especially in chronic disease. Up to 85% of synovial fluid samples are positive in active arthritis. In contrast, 38% of CSF samples in acute neuroborreliosis are PCR positive, and only 25% are positive in chronic neuroborreliosis. The significance of a positive reaction is unclear. Whether a positive PCR indicates persistence of viable organisms that will respond to further treatment or is a marker for residual DNA (not active infection) has not been clarified. A negative PCR result does not rule out disease.

### Complications

Several observational studies, including serosurveys of over 2000 pregnant women in endemic areas, and case control studies of nearly 800 infants with congenital heart disease have not found any association between seropositivity or tick exposure in prospective mothers and the prevalence of congenital malformations, fetal death, and prematurity. Thus, if *B. burgdorferi* causes a congenital syndrome like some other spirochetal illnesses, it must be extremely uncommon.

### Prevention

There is no human vaccine currently available. Simple preventive measures such as avoiding tick-infested areas, covering exposed skin with long-sleeved shirts and wearing long trousers tucked into socks, wearing light-colored clothing, using repellents, and inspecting for ticks after exposure will greatly reduce the number of tick bites. Environmental controls directed at limiting ticks on residential property would be helpful, but trying to limit the deer, tick, or white-footed mouse populations over large areas is not feasible.

Prophylactic antibiotics following tick bites is recommended in certain high risk situations if all of the following criteria are met: (1) a tick identified as an adult or nymphal *I. scapularis* has been attached for at least 36 hours; (2) prophylaxis can be started within 72 hours of the time the tick was removed; (3) more than 20% of ticks in the area are known to be infected with *B. burgdorferi*; and (4) there is no contraindication to the use of doxycycline (not pregnant, age > 8 years, not allergic). As noted above, *I. scapularis* ticks in the northeastern, mid-Atlantic, and upper midwestern states are infected with *B. burgdorferi* at a high rate (> 20%) whereas *I. pacificus* ticks on the West Coast are not (about 2%). The drug of choice for prophylaxis is a single 200 mg dose of doxycycline. If doxycycline is contraindicated, no prophylaxis should be given, since short course prophylactic therapy with other agents has not been studied and if early disease does develop appropriate therapy is very effective in preventing long-term sequelae. Individuals who have removed ticks (including those who have had prophylaxis) should be monitored carefully for 30 days for possible coinfections.

#### Coinfections

Lyme disease, babesiosis (see Chapter 35), and human granulocytic anaplasmosis (formerly human granulocytic ehrlichiosis) (see Chapter 32) are endemic in similar areas of the country and are transmitted by the same tick, *I. scapularis*. Coinfection with two or even all three of these organisms can occur, causing a clinical picture that is not “classic” for any of these diseases. The presence of erythema migrans is highly suggestive of Lyme disease, whereas flu-like symptoms without rash are more suggestive of babesiosis or anaplasmosis. The complete blood count is usually normal in Lyme disease, but in patients with Lyme disease and babesiosis, anemia and thrombocytopenia are more common. Patients with Lyme disease and anaplasmosis are more likely to have leukopenia. Coinfection should be considered and excluded in patients who have persistent high fevers 48 hours after starting appropriate therapy for Lyme disease; in patients with persistent symptoms despite resolution of rash; and in those with anemia, leukopenia, or thrombocytopenia.

Even in patients with documented Lyme disease, immunity is not complete. Reinfection, although uncommon, is predominantly seen in patients successfully treated for early disease (erythema migrans) who do not develop antibody titers. Clinical manifestations and serologic response is similar to an initial infection.

### Treatment

Present recommendations for therapy are outlined in Table 34–4. For erythema migrans, antibiotic therapy shortens the duration of rash and prevents late sequelae. Doxycycline is most commonly used and has the advantage of being active against *Anaplasma phagocytophilum* (formerly *Ehrlichia*). Amoxicillin is also effective and is recommended for pregnant or lactating women and for those who cannot tolerate doxycycline. Cefuroxime axetil, is as effective as doxycycline, but because of its cost it should be considered an alternative choice for those who cannot tolerate doxycycline or amoxicillin or for those in whom the drugs are contraindicated. Erythromycin and azithromycin are less effective, associated with higher rates of relapse, and are not recommended as first-line therapy.

Isolated facial palsy (without meningitis or peripheral neuropathy) can be treated with doxycycline, amoxicillin, or cefuroxime axetil for 2–3 weeks. Although therapy does not affect the rate of resolution of the cranial neuropathy, it does prevent development of late manifestations of disease.

The need for a lumbar puncture in patients with seventh nerve palsy is controversial. Some clinicians perform lumbar puncture on all patients with facial palsy and others only if there are symptoms or signs of meningitis. If meningitis is present, therapy with a parenteral antibiotic is indicated. Ceftriaxone is most commonly used, but penicillin is equally efficacious. In European countries, doxycycline 400 mg/d orally for 14 days is frequently used and is comparable in efficacy to ceftriaxone.

Patients with atrioventricular block or myopericarditis (or both) can be treated with either oral or parenteral agents for 2–3 weeks. Hospitalization and observation is indicated for symptomatic patients, those with second- or third-degree block, and those with first-degree block with
a PR interval ≥ 300 milliseconds. Once stabilized, hospitalized patients can be transitioned to one of the oral regimens to complete therapy.

Therapy of arthritis is difficult because some patients do not respond to any therapy, and those who do respond may do so slowly. Oral agents (doxycycline, amoxicillin, or cefuroxime axetil) are as effective as intravenous regimens (ceftriaxone, cefotaxime, or penicillin G). A reasonable approach to the patient with Lyme arthritis is to start with oral therapy for 28 days, and if this fails (persistent or recurrent joint swelling), to re-treat with an oral regimen for 28 days or switch to an intravenous regimen for 2–4 weeks. If some improvement has occurred with initial treatment with an oral regimen, another course of oral therapy is reasonable. If there has been no response or worsening with initial oral therapy, a parenteral regimen should be used. Re-treatment should be delayed for several months because of the slow resolution of joint symptoms. If arthritis persists after re-treatment, symptomatic therapy with nonsteroidal anti-inflammatory drugs is recommended. For severe refractory pain, synovectomy may be required.

Based on the limited published data, therapy of Lyme disease in pregnancy should be the same as therapy in other patients with the exception that doxycycline should not be used.

Clinicians are often confronted with patients with nonspecific symptoms (such as fatigue and myalgias) and positive serologic tests for Lyme disease who request (or demand) therapy for their illness. It is important in managing these patients to remember (1) that the diagnosis of Lyme disease is primarily a clinical one, and nonspecific symptoms alone are not diagnostic; (2) that serologic tests are fraught with difficulty (as noted above), and in areas where disease prevalence is low, false-positive serologic tests are much more common than true-positive tests; and (3) that parenteral therapy with ceftriaxone for 2–4 weeks is costly and has been associated with significant adverse effects, including cholelithiasis and *Clostridium difficile* colitis. Parenteral therapy should be reserved for those most likely to benefit, ie, those with cutaneous, neurologic, cardiac, or rheumatic manifestations that are characteristic of Lyme disease.

### Prognosis

Most patients respond to appropriate therapy with prompt resolution of symptoms within 4 weeks. True treatment failures are thus uncommon, and in most cases re-treatment or prolonged treatment of Lyme disease is instituted because of misdiagnosis or misinterpretation of serologic results (both IgG and IgM antibodies can persist for prolonged periods despite adequate therapy) rather than inadequate therapy or response. Prolonged courses of antibiotic therapy for nonspecific symptoms that persist after completion of appropriate assessment (and treatment, if necessary) for Lyme disease is not recommended.

The long-term outcome of adult patients with Lyme disease is generally favorable, but some patients have chronic complaints. Joint pain, memory impairment, and poor functional status secondary to pain are common subjective complaints in patients with Lyme disease, but physical examination and neurocognitive testing fail to document the presence of these symptoms as objective sequelae. Similarly, in highly endemic areas, patients with a diagnosis of Lyme disease commonly complain of pain, fatigue, and an inability to perform certain physical activities when followed for several years. However, these complaints occur just as commonly in age-matched controls without a history of Lyme disease. Attempts to document chronic cardiac disease in patients treated for Lyme disease also have been unsuccessful. The long-term outcome of treated neuroborelliosis is favorable, with complete recovery in 75% of patients. Of the remaining
individuals, only 12% had sequelae that affected their daily activities.

When to Refer

Consultation with an infectious diseases specialist with experience in diagnosing and treating Lyme disease can be helpful in atypical or prolonged cases.

When to Admit

Admission for parenteral antibiotics is indicated for any patient with symptomatic central nervous system or cardiac disease as well as those with second- or third-degree atrioventricular block, or first-degree block with a PR interval ≥ 300 milliseconds.

Protozoal Infections

African Trypanosomiasis (Sleeping Sickness)

**Essentials of Diagnosis**

- Exposure to tsetse flies; chancre at bite site uncommon.
- **Hemolymphatic disease**: Irregular fever, headache, joint pain, rash, edema, lymphadenopathy.
- **Meningoencephalitic disease**: Somnolence, severe headache, progressing to coma.
- Trypanosomes in blood or lymph node aspirates; positive serologic tests.
- Trypanosomes and increased white cells and protein in cerebrospinal fluid.

**Clinical Findings**

**A. Symptoms and Signs**

1. **West African trypanosomiasis**—Chances at the site of the bite are uncommon. After an asymptomatic period that may last for months, **hemolymphatic disease** presents with fever, headache, myalgia, arthralgia, weight loss, and lymphadenopathy, with discrete, nontender, rubbery nodes, referred to as Winterbottom sign when in a posterior cervical distribution. Other common signs are mild splenomegaly, transient edema, and a pruritic erythematous rash. Febrile episodes may be broken by afebrile periods of up to several weeks. The hemolymphatic stage progresses over months to **meningoencephalitic disease**, with somnolence, irritability, personality changes, severe headache, and parkinsonian symptoms progressing to coma and death.

2. **East African trypanosomiasis**—Chances at the bite site are more commonly recognized with **T b rhodesiense** infection, with a painful lesion of 3–10 cm and regional lymphadenopathy that appears about 48 hours after the tsetse fly bite and lasts 2–4 weeks. East African disease follows a much more acute course, with the onset of symptoms usually within a few days of the insect bite. The hemolymphatic stage includes intermittent fever and rash, but lymphadenopathy is less common than with West African disease. Myocarditis can cause tachycardia and death due to arrhythmias or heart failure. If untreated, East African trypanosomiasis progresses over weeks to months to meningoencephalitic disease, somnolence, coma, and death.

**B. Laboratory Findings**

Diagnosis can be difficult, and definitive diagnosis requires identification of trypanosomes. Microscopic examination of fluid expressed from a chancre or lymph node may show control has been disrupted by civil strife. The largest number of cases is in the Democratic Republic of the Congo. Annual incidence estimates are about 100,000 cases and 48,000 deaths, mostly due to **T b gambiense**, leading to the loss of 1.5 million disability-adjusted life years. Infections are rare among travelers, including visitors to game parks.
motile trypanosomes or, in fixed specimens, parasites stained with Giemsa. During the hemolymphatic stage, detection of parasites in Giemsa-stained blood smears is common in East African disease but difficult in West African disease. Serial specimens should be examined, since parasitemias vary greatly over time. Meningoencephalitic (or second stage) disease is defined by the World Health Organization (WHO) as cerebrospinal fluid (CSF) showing at least five mononuclear cells per microliter, elevated protein, or presence of trypanosomes. Concentration techniques can aid identification of parasites in blood or CSF. Serologic tests are also available. The simple card agglutination test for trypanosomes (CATT) has excellent sensitivity and specificity for West African disease and can be performed in the field; however, the diagnosis should be confirmed by identification of the parasites.

**Treatment**

Detection of trypanosomes is a prerequisite for treatment of African trypanosomiasis because of the significant toxicity of most available therapies. Treatment recommendations depend on the type of trypanosomiasis (Table 35–1), which is determined by geography, and stage of disease, which requires examination of CSF.

A. **West African Trypanosomiasis**

1. **Early stage infection**—Pentamidine (4 mg/kg intramuscularly or intravenously every day or every other day for 7 days) is used to treat infection that does not involve the central nervous system (CNS). The side effects of pentamidine include immediate hypotension; tachycardia; gastrointestinal symptoms during administration; sterile abscesses; and pancreatic (hypoglycemia), liver, and kidney abnormalities. An alternate drug is eflornithine (100 mg/kg/d intravenously every 6 hours for 14 days).

2. **Late stage infection**—Eflornithine is the drug of choice for infection that involves the CNS; the dosage is the same as that used to treat early disease. Eflornithine has less toxicity than older trypanocidal drugs, but it can cause gastrointestinal symptoms and bone marrow suppression and is limited by lack of availability and the need for infusions four times daily. Alternative therapies are melarsoprol (see below) or nifurtimox (5 mg/kg orally three times per day for 14 days), and drug combinations (eg, oral nifurtimox plus twice-daily eflornithine) may offer improved efficacy over monotherapies, with simplified regimens and decreased toxicity.

B. **East African Trypanosomiasis**

Pentamidine and eflornithine are not reliably effective, and early disease is treated with suramin. The dosing regimens of suramin vary (eg, 100–200 mg test dose, then 20 mg/kg [maximum 1 g] intravenously on days 1, 3, 7, 14, and 21 or weekly for 5 doses). Suramin toxicities include vomiting and, rarely, seizures and shock during infusions as well as subsequent fever, rash, headache, neuropathy, and kidney and bone marrow dysfunction.

Suramin does not enter the CNS, so East African trypanosomiasis involving the CNS is treated with melarsoprol (three series of 3.6 mg/kg/d intravenously for 3 days, with 7-day breaks between the series or a 10-day intravenous course with 0.6 mg/kg on day 1, 1.2 mg/kg on day 2, and 1.8 mg/kg on days 3–10). Melarsoprol also acts against West African disease, but eflornithine is preferred due to its lower toxicity. Immediate side effects of melarsoprol include fever and gastrointestinal symptoms. The most important side effect is a reactive encephalopathy that can progress to seizures, coma, and death. To help avoid this side effect, corticosteroids are coadministered (recommended regimens include dexamethasone 1 mg/kg/d intravenously for 2–3 days or oral prednisolone 1 mg/kg/d for 5 days, and then 0.5 mg/kg/d until treatment completion). In addition, increasing resistance to melarsoprol is a serious concern. Suramin and melarsoprol are available in the United States from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333; telephone: 404-639-3670.

**Prevention & Control**

Individual prevention in endemic areas should include long sleeves and pants, insect repellents, and mosquito nets. Control programs focusing on vector elimination and treatment of infected persons and animals have shown good success in many areas but suffer from limited resources.

CNS, central nervous system.
AMERICAN TRYPAansomIASis (Chagas Disease)

ESSENTIALS OF DIAGNOSIS

Acute stage
- Inflammatory lesion at inoculation site.
- Fever.
- Hepatosplenomegaly.
- Lymphadenopathy.
- Myocarditis.
- Parasites in blood is diagnostic.

Chronic stage
- Heart failure, cardiac arrhythmias.
- Thromboembolism.
- Megaesophagus.
- Megacolon.
- Serologic tests are usually diagnostic.

General Considerations

Chagas disease is caused by Trypanosoma cruzi, a protozoan parasite found only in the Americas; it infects wild animals and to a lesser extent humans from southern South America to the southern United States. An estimated 10–12 million people are infected, mostly in rural areas. Recent control efforts in endemic countries have decreased disease incidence to about 40,000 new infections and 12,500 deaths per year. The disease is often acquired in childhood. In many countries in South America, Chagas disease is the most important cause of heart disease. In the United States, the vector is found and some animals are infected, but only a few instances of local transmission have been reported.

T. cruzi is transmitted by reduviid (triatomine) bugs infected by ingesting blood from animals or humans who have circulating trypanosomes. Multiplication occurs in the digestive tract of the bug and infective forms are eliminated in feces. Infection in humans occurs when the parasite penetrates the skin through the bite wound, mucous membranes, or the conjunctiva. Transmission can also occur by blood transfusion, organ or bone marrow transplantation, congenital transfer, or ingestion of food contaminated with vector feces. From the bloodstream, T. cruzi invades many cell types but has a predilection for myocardium, smooth muscle, and CNS glial cells. Multiplication causes cellular destruction, inflammation, and fibrosis, with progressive disease over decades.

Clinical Findings

A. Symptoms and Signs

As many as 70% of infected persons remain asymptomatic. The acute stage is seen principally in children and lasts 1–2 months. The earliest findings are at the site of inoculation either in the eye—Romana sign (unilateral edema, conjunctivitis, and lymphadenopathy)—or in the skin—a chagoma (swelling with local lymphadenopathy). Subsequent findings include fever, malaise, headache, mild hepatosplenomegaly, and generalized lymphadenopathy. Acute myocarditis and meningoencephalitis are rare but can be fatal.

An asymptomatic latent period (indeterminate phase) may last for life, but symptomatic disease develops in 10–30% of infected individuals, commonly many years after infection.

Chronic Chagas disease generally manifests as abnormalities in cardiac and smooth muscle. Cardiac disease includes arrhythmias, congestive heart failure, and embolic disease. Smooth muscle abnormalities lead to mega-esophagus and megacolon, with dysphagia, regurgitation, aspiration, constipation, and abdominal pain. These findings can be complicated by superinfections. In immunosuppressed persons, including AIDS patients and transplant recipients, latent Chagas disease may reactivate; findings have included brain abscesses and meningoencephalitis.

B. Diagnostic Testing

Diagnosis should be considered in persons with suggestive findings who have resided in an endemic area. Transmission by blood transfusion and congenital transmission should also be considered. The diagnosis is made by detecting parasites. With acute infection, evaluation of fresh blood or buffy coats may show motile trypanosomes, and fixed preparations may show Giemsa-stained parasites. Trypanosomes may be identified in lymph nodes, bone marrow, or pericardial or spinal fluid. When initial tests are unrevealing in a suspicious case, xenodiagnosis using laboratory vectors, laboratory culture, or animal inoculation may provide a diagnosis, but these methods are expensive and slow.

Chronic Chagas disease is usually diagnosed serologically. Many different serologic assays are available, but sensitivity and specificity are not ideal, so confirmatory assays are advised after an initial positive test, as is standard for blood bank testing in South America. Polymerase chain reaction (PCR) may offer an important new modality for diagnosis, but sensitivity of PCR assays has been disappointing.

Treatment

Treatment is inadequate because the two drugs used, nifurtimox and benznidazole, often cause severe side effects, must be used for long periods, and are ineffective against chronic infection. In acute and congenital infections, the drugs can reduce the duration and severity of infection, but cure is achieved in only about 70% of patients. During the chronic phase of infection, although parasitemia may disappear in up to 70% of patients, treatment does not clearly alter the progression of the disease. Nevertheless, there is general consensus that treatment should be considered in all T. cruzi-infected persons regardless of clinical status or time since infection. In particular, treatment is recommended for acute, congenital, and reactivated infections and for children and young adults with chronic disease.
Nifurtimox is given orally in daily doses of 8–10 mg/kg in four divided doses after meals for 90–120 days. Side effects include gastrointestinal (anorexia, vomiting) and neurologic (headaches, ataxia, insomnia, seizures) symptoms, which appear to be reversible and to lessen with dosage reduction. Benznidazole is an alternative therapy that is given orally at a dosage of 5 mg/kg/d in divided doses for 60 days. Its side effects include granulocytopenia, rash, and peripheral neuropathy. In the United States, nifurtimox is available from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333; telephone: 404-639-3670. Patients with chronic Chagas disease may also benefit from antiarrhythmic therapy, standard therapy for congestive heart failure, and conservative and surgical management of megasophasus and megacolon.

### General Considerations

Leishmaniasis is a zoonosis transmitted by bites of sand flies of the genus *Lutzomyia* in the Americas and *Phlebotomus* elsewhere. When sand flies feed on an infected host, the parasitized cells are ingested with the blood meal. Leishmaniasis is caused by about 20 species of *Leishmania*; taxonomy is complex. Clinical syndromes are generally dictated by the infecting species, but some species can cause more than one syndrome.

An estimated 350 million persons are at risk for leishmaniasis. The estimated annual incidence of disease is 1–1.5 million new cases of cutaneous and 500,000 cases of visceral disease, leading to an estimated 50,000–60,000 deaths. The incidence of disease is increasing in many areas.

**Visceral leishmaniasis** (kala azar) is caused mainly by *Leishmania donovani* in the Indian subcontinent and East Africa; *Leishmania infantum* in the Mediterranean, Middle East, China, parts of Asia, and Horn of Africa; and *Leishmania chagasi* in South and Central America. Other species may occasionally cause visceral disease. Over 90% of cases occur in five countries: India, Bangladesh, Nepal, Sudan, and Brazil. In each locale, the disease has particular clinical and epidemiologic features. The incubation period is usually 4–6 months (range: 10 days to 24 months). Without treatment, the fatality rate reaches 90%. Early diagnosis and treatment reduces mortality to 2–5%.

**Old World cutaneous leishmaniasis** is caused mainly by *Leishmania tropica*, *Leishmania major*, and *Leishmania aethiopica* in the Mediterranean, Middle East, Africa, Central Asia, and Indian subcontinent. **New World cutaneous leishmaniasis** is caused by *Leishmania mexicana* and *Leishmania amazonensis* in Central and South America. **Mucocutaneous leishmaniasis** (espundia) occurs in lowland forest areas of the Americas and is caused by *Leishmania braziliensis*, *Leishmania panamensis*, and *Leishmania peruviana*.

### Clinical Findings

#### A. Symptoms and Signs

1. **Visceral leishmaniasis (kala azar)**—Most infections are subclinical, but a small number progress to full-blown disease. A local nonulcerating nodule at the site of the sand fly bite may precede systemic manifestations but usually is inapparent. The onset of illness may be acute, within 2 weeks of infection, or insidious. Symptoms and signs include fever, chills, sweats, weakness, anorexia, weight loss, cough, and diarrhea. The spleen progressively becomes greatly enlarged, firm, and nontender. The liver is somewhat enlarged, and generalized lymphadenopathy may occur. Hyperpigmentation of skin can be seen, leading to the name kala azar (“black fever”). Other signs include skin lesions, petechiae, gingival bleeding, jaundice, edema, and ascites. As the disease progresses, severe wasting and malnutrition are seen; death eventually occurs, often due to secondary infections, within months to a few years. Post-kala azar dermal leishmaniasis may appear after apparent cure in the Indian subcontinent and Sudan. It may simulate leprosy, with hypopigmented macules or nodules...
developing on preexisting lesions. Viscerotropic leishmaniasis has been reported in small numbers of American military personnel in the Middle East, with mild systemic febrile illnesses after \( L \) tropica infections.

2. Old World and New World cutaneous leishmaniasis—
Cutaneous swellings appear 2 weeks to several months after sand fly bites and can be single or multiple. Characteristics of lesions and courses of disease vary depending on the leishmanial species and host immune response. Lesions begin as small papules and develop into nonulcerated dry plaques or large encrusted ulcers with well-demarcated raised and indurated margins (Figure 35–1). Satellite lesions may be present. The lesions are painless unless secondarily infected. Local lymph nodes may be enlarged. Systemic symptoms are uncommon, but fever, constitutional symptoms, and regional lymphadenopathy may be seen. For most species, healing occurs spontaneously in months to a few years, but scarring is commonly seen.

Leishmaniasis recidivans is a relapsing form of \( L \) tropica infection associated with hypersensitivity, in which the primary lesion heals centrally, but spreads laterally, with extensive scarring. Diffuse cutaneous leishmaniasis involves spread from a central lesion to local dissemination of nodules and a protracted course. Disseminated cutaneous leishmaniasis involves multiple nodular or ulcerated lesions, often with mucosal involvement.

3. Mucocutaneous leishmaniasis (espundia)—In Latin America, mucosal lesions develop in a small percentage of persons infected with \( L \) braziliensis and some other species, usually months to years after resolution of a cutaneous lesion. Nasal congestion is followed by ulceration of the nasal mucosa and septum, progressing to involvement of the mouth, lips, palate, pharynx, and larynx. Extensive destruction can occur, and secondary bacterial infection is common.

4. Infections in patients with AIDS—Leishmaniasis is an opportunistic infection in persons with AIDS seen in southern Europe and other areas. Visceral leishmaniasis can present late in the course of HIV infection, with fever, hepatosplenomegaly, and pancytopenia. The gastrointestinal tract, respiratory tract, and skin may also be involved.

B. Laboratory Findings
Identifying parasites in tissue samples or culture material provides a definitive diagnosis. In visceral leishmaniasis, fine-needle aspiration of the spleen for culture and tissue evaluation is generally safe, and yields a diagnosis in over 95% of cases. Bone marrow aspiration is less sensitive but safer and diagnostic in most cases. Giemsa-stained buffy coat of peripheral blood may occasionally show organisms. For all tissue biopsies and touch preparations, Giemsa staining will show amastigotes within macrophages. Cultures with media available from the CDC will grow promastigotes within a few days to weeks. PCR can also identify the infection. Inoculation of laboratory animals can also be used but is time consuming. Species are identified by molecular, isoenzyme, and monoclonal antibody methods. Serologic tests may facilitate diagnosis, but none are sufficiently sensitive or specific to be used alone. Antibody levels are typically high with visceral leishmaniasis but not cutaneous disease. For cutaneous lesions, biopsies should be taken from the raised border of a skin lesion, with samples for histopathology, touch preparation, and culture. The histopathology shows inflammation with mononuclear cells. Macrophages filled with amastigotes may be present, especially early in infection. An intradermal leishmanin (Montenegro) skin test is positive in most individuals with cutaneous disease but negative in those with progressive visceral or diffuse cutaneous disease; this test is not approved in the United States. In mucocutaneous leishmaniasis, diagnosis is established by detecting amastigotes in scrapings, biopsy preparations, or aspirated tissue fluid, but organisms may be rare. Cultures from these samples may grow organisms. Serologic studies are often negative, but the leishmanin skin test is usually positive.

Treatment

A. Visceral Leishmaniasis
The treatment of choice for visceral leishmaniasis is liposomal amphotericin B, which is generally effective and well tolerated but very expensive. Liposomal amphotericin B is approved for this use in the United States. Standard dosing is 3 mg/kg/d intravenously on days 1–5, 14, and 21. Conventional amphotericin B deoxycholate, which is much less expensive, is also highly effective but with more toxicity. It is administered as a slow intravenous infusion of 1 mg/kg/d for 15–20 days or 0.5–1 mg/kg every second day for up to 8 weeks. Infusion-related side effects with conventional or liposomal amphotericin B include gastrointestinal symptoms, fever, chills, dyspnea, hypotension, and hepatic and renal toxicity.

Pentavalent antimonials remain the most commonly used drugs to treat leishmaniasis in most areas. Response rates are good outside India, but in India, resistance is a major problem. Two preparations are available, sodium stibogluconate in the United States and many other...
areas and meglumine antimonate in Latin America and francophone countries; the compounds appear to have comparable activities. In the United States, sodium stibogluconate can be obtained from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333; telephone: 404-639-3670.

Treatment with either antimonial is given once daily at a dose of 2.5 mg/kg/d intravenously (preferred) or intramuscularly for 20 days for cutaneous leishmaniasis and 28 days for visceral or mucocutaneous disease. Toxicity increases over time, with development of gastrointestinal symptoms, fever, headache, myalgias, arthralgias, pancreatitis, and rash. Intramuscular injections can cause sterile abscesses. Monitoring should include serial ECGs, and changes are indications for discontinuation to avoid progression to serious arrhythmias.

Miltefosine is the first oral drug for the treatment of leishmaniasis, and it provides excellent results in India, where resistance to antimonials is increasing. It can be administered at a daily oral dose of 2.5 mg/kg in two divided doses for 28 days. A 28-day course of miltefosine (2.5 mg/kg/d) is also effective for the treatment of New World cutaneous leishmaniasis. Vomiting, diarrhea, and elevations in transaminases and kidney function studies are common, but generally short-lived, side effects. Miltefosine is registered for the treatment of visceral leishmaniasis in India and may become the standard of care, in particular in combination regimens, in that country.

Pentamidine isethionate is an alternative therapy for visceral leishmaniasis, given daily or on alternate days for 15 doses of 2–4 mg/kg intramuscularly or intravenously. Side effects include immediate hypotension; tachycardia; and gastrointestinal symptoms during administration; sterile abscesses; and pancreatic, liver, and kidney abnormalities.

The aminoglycoside paromomycin (11 mg/kg/d intramuscularly for 21 days) was shown to be similarly efficacious to amphotericin B for the treatment of visceral disease in India. It is much less expensive than liposomal amphotericin B or miltefosine. Of note, paromomycin has shown relatively poor efficacy in studies in Africa. Approval of an intramuscular preparation for visceral leishmaniasis was received in India in 2006. The drug is well tolerated; side effects include otoxicity and reversible elevations in liver enzymes.

There is increasing interest in combination treatment regimens for visceral leishmaniasis to shorten treatment courses, save costs, and prevent the selection of resistant parasites. Resistance is of particular concern; laboratory studies suggest that resistance to miltefosine and paromomycin may be readily selected by monotherapy regimens. In India, regimens including a 10-day course of miltefosine plus paromomycin or a single dose of liposomal amphotericin B combined with either 7 days of oral miltefosine or 10 days of paromomycin were all noninferior to a 15-dose regimen of conventional amphotericin B. Based on these and other similar results, combination regimens may become the treatments of choice for visceral leishmaniasis in India.

**B. Cutaneous Leishmaniasis**

In the Old World, cutaneous leishmaniasis is generally self-healing over some months and does not metastasize to the mucosa, so it may be justified to withhold treatment in regions without mucocutaneous disease if lesions are small and cosmetically unimportant. Lesions on the face or hands are generally treated. New World leishmaniasis has a greater risk of progression to mucocutaneous disease, so treatment is more often warranted. Standard therapy is with pentavalent antimonials for 20 days, as described above. Other treatments include those discussed above for visceral disease,azole antifungals, and allopurinol. In studies in Brazil, a 28-day course of miltefosine was superior to a 20-day course of meglumine antimoniate, and oral fluconazole also showed good efficacy. Topical therapy has included intralesional antimony, paromomycin ointment, cryotherapy, local heat, and surgical removal. Diffuse cutaneous leishmaniasis and related chronic skin processes generally respond poorly to therapy.

**C. Mucocutaneous Leishmaniasis**

Cutaneous infections from regions where parasites include those that cause mucocutaneous disease (eg, *L. braziliensis* in parts of Latin America) should all be treated to help prevent disease progression. Treatment of mucocutaneous disease with antimonials is disappointing, with responses in only about 60% in Brazil. Other therapies listed above for visceral leishmaniasis may also be used, although they have not been well studied for this indication.

**Prevention & Control**

Personal protection measures for avoidance of sand fly bites include use of insect repellants, fine-mesh insect netting, long sleeves and pants, and avoidance of warm shaded areas where flies are common. Disease control measures include destruction of animal reservoir hosts, mass treatment of humans in disease-prevalent areas, residual insecticide spraying in dwellings, limiting contact with dogs and other domesticated animals, and use of permethrin-impregnated collars for dogs.

MALARIA

ESSENTIALS OF DIAGNOSIS

- Residence or exposure in a malaria-endemic area.
- Intermittent attacks of chills, fever, and sweating.
- Headache, myalgia, vomiting, splenomegaly; anemia, thrombocytopenia.
- Intraerythrocytic parasites identified in thick or thin blood smears.
- Complications of falciparum malaria: cerebral malaria, severe anemia, hypotension, noncardiogenic pulmonary edema, acute kidney injury, hypoglycemia, acidosis, and hemolysis.

General Considerations

Malaria is the most important parasitic disease of humans, causing hundreds of millions of illnesses and nearly a million deaths each year. The disease is endemic in most of the tropics, including much of South and Central America, Africa, the Middle East, the Indian subcontinent, Southeast Asia, and Oceania. Transmission, morbidity, and mortality are greatest in Africa, where most deaths from malaria are in young children. Malaria is also common in travelers from nonendemic areas to the tropics.

Four species of the genus Plasmodium classically cause human malaria. Plasmodium falciparum is responsible for nearly all severe disease. It is endemic in most malarious areas and is by far the predominant species in Africa. Plasmodium vivax is about as common as P. falciparum, except in Africa. P. vivax uncommonly causes severe disease, although this outcome may be more common than previously appreciated. Plasmodium ovale and Plasmodium malariae are much less common causes of disease, and generally do not cause severe illness. Plasmodium knowlesi, a parasite of macaque monkeys, is now recognized to cause occasional illnesses, including some severe disease, in humans in Southeast Asia.

Malaria is transmitted by the bite of infected female anopheline mosquitoes. During feeding, mosquitoes inject sporozoites, which circulate to the liver, and rapidly infect hepatocytes, causing asymptomatic liver infection. Merozoites are subsequently released from the liver, and they rapidly infect erythrocytes to begin the asexual erythrocytic stage of infection that is responsible for human disease. Multiple rounds of erythrocytic development, with production of merozoites that invade additional erythrocytes, lead to large numbers of circulating parasites and clinical illness. Some erythrocytic parasites also develop into sexual gametocytes, which are infectious to mosquitoes, allowing completion of the life cycle and infection of others.

Malaria may uncommonly be transmitted from mother-to-infant (congenital malaria), by blood transfusion, and in nonendemic areas by mosquitoes infected after biting infected immigrants or travelers. In P. vivax and P. ovale, parasites also form dormant liver hypnozoites, which are not killed by most drugs, allowing subsequent relapses of illness after initial elimination of erythrocytic infections. For all plasmodial species, parasites may recrudesce following initial clinical improvement after suboptimal therapy.

In highly endemic regions, where people are infected repeatedly, antimalarial immunity prevents severe disease in most older children and adults. However, young children, who are relatively nonimmune, are at high risk for severe disease from P. falciparum infection, and this population is responsible for most deaths from malaria. Pregnant women are also at increased risk for severe falciparum malaria. In areas with lower endemicity, individuals of all ages commonly present with uncomplicated or severe malaria. Travelers, who are generally nonimmune, are at high risk for severe disease from falciparum malaria at any age.

Clinical Findings

A. Symptoms and Signs

An acute attack of malaria typically begins with a prodrome of headache and fatigue, followed by fever. A classic malarial paroxysm includes chills, high fever, and then sweats. Patients may appear to be remarkably well between febrile episodes. Fevers are usually irregular, especially early in the illness, but without therapy may become regular, with 48-hour cycles (P. vivax and P. ovale) or 72-hour cycles (P. malariae), especially with non-falciparum disease. Headache, malaise, myalgia, arthralgia, cough, chest pain, abdominal pain, anorexia, nausea, vomiting, and diarrhea are common. Seizures may represent simple febrile convulsions or evidence of severe neurologic disease. Physical findings may be absent or include signs of anemia, jaundice, splenomegaly, and mild hepatomegaly. Rash and lymphadenopathy are not typical in malaria, and thus suggestive of another cause of fever.

In the developed world, it is imperative that all persons with suggestive symptoms, in particular fever, who have traveled in an endemic area be evaluated for malaria. The risk for falciparum malaria is greatest within 2 months of return from travel; other species may cause disease many months—and occasionally more than a year—after return from an endemic area.

Severe malaria is defined as the presence of signs of severe illness or organ dysfunction or a high parasite load...
(peripheral parasitemia > 5% or > 200,000 parasites/mL). It is principally a result of *P. falciparum* infection because this species uniquely infects erythrocytes of all ages and mediates the sequestration of infected erythrocytes in small blood vessels, thereby evading clearance of infected erythrocytes by the spleen.

Severe falciparum malaria can include dysfunction of any organ system, including neurologic abnormalities progressing to alterations in consciousness, repeated seizures, and coma (cerebral malaria); severe anemia; hypotension and shock; noncardiogenic pulmonary edema and the acute respiratory distress syndrome; acute kidney injury due to acute tubular necrosis or, less commonly, severe hemolysis; hypoglycemia; acidosis; hemolysis with jaundice; hepatic dysfunction; retinal hemorrhages and other fundoscopic abnormalities; bleeding abnormalities, including disseminated intravascular coagulation; and secondary bacterial infections, including pneumonia and *Salmonella* bacteremia. In the developing world, severe malaria and deaths from the disease are mostly in young children, in particular from cerebral malaria and severe anemia. Cerebral malaria is a consequence of a single severe infection while severe anemia follows multiple malarial infections, intestinal helminths, and nutritional deficiencies.

Uncommon disorders resulting from immunologic responses to chronic infection are massive splenomegaly and, with *P. malariae* infection, immune complex glomerulopathy with nephrotic syndrome. HIV-infected individuals are at increased risk for malaria and for severe disease, in particular with advanced immunodeficiency.

### B. Laboratory Findings

Giemsa-stained blood smears remain the mainstay of diagnosis (Figures 35–2 through 35–5), although other routine stains (eg, Wright stain) will also demonstrate parasites. Thick smears provide efficient evaluation of large volumes of blood, but thin smears are simpler for inexperienced personnel and better for discrimination of parasite species. Single smears are usually positive in infected individuals,
Malaria is the most common cause of fever in much of the tropics and in travelers seeking medical attention after return from endemic areas. Fevers are often treated presumptively in endemic areas, but ideally, treatment should follow definitive diagnosis, especially in non-immune individuals (see Tables 35–4 and 35–5).

Symptomatic malaria is caused only by the erythrocytic stage of infection. Available antimalarial drugs (Table 35–2) act against this stage, except for primaquine, which acts principally against hepatic parasites.

### A. Non-Falciparum Malaria

The first-line drug for non-falciparum malaria from most areas remains chloroquine. Due to increasing resistance of *P. vivax* to chloroquine, alternative therapies are recommended when resistance is suspected, particularly for infections acquired in Indonesia, Oceania, and Peru. These infections can be treated with artemisinin-based combination therapies or other first-line regimens for *P. falciparum* infections as discussed below. For *P. vivax* or *P. ovale*, eradication of erythrocytic parasites with chloroquine should be accompanied by treatment with primaquine (after evaluating for glucose-6-phosphate dehydrogenase [G6PD] deficiency; see below) to eradicate dormant liver stages (hypnozoites), which may lead to relapses with recurrent erythrocytic infection and malaria symptoms after weeks although parasitemias may be very low in nonimmune individuals. If illness is suspected, repeating smears in 8- to 24-hour intervals is appropriate. The severity of malaria correlates only loosely with the quantity of infecting parasites, but high parasitemias (especially >10–20% of erythrocytes infected or >200,000–500,000 parasites/ml) or the presence of malarial pigment (a breakdown product of hemoglobin) in >5% of neutrophils are associated with a particularly poor prognosis.

A second means of diagnosis is rapid diagnostic tests to identify circulating plasmodial antigens with a simple “dip-stick” format. These tests are not well standardized but are increasingly available around the world, including in the United States. At best, they offer sensitivity and specificity near that of high-quality blood smear analysis and are simpler to perform.

Serologic tests indicate history of disease but are not useful for diagnosis of acute infection. PCR is highly sensitive but not available for routine diagnosis. In immune populations, highly sensitive tests, such as PCR, have limited value because subclinical infections, which are of uncertain significance and not routinely treated, are common.

Other diagnostic findings with uncomplicated malaria include thrombocytopenia, anemia, leukocytosis or leukopenia, liver function abnormalities, and hepatosplenomegaly. Severe malaria can present with the laboratory abnormalities expected for the advanced organ dysfunction discussed above.

### Table 35–2. Major antimalarial drugs.

| Drug                          | Class                        | Use                                                               |
|-------------------------------|------------------------------|                                                                  |
| Chloroquine                   | 4-Aminoquinoline             | Treatment and chemoprophylaxis of infection with sensitive parasites |
| Amodiaquine<sup>1</sup>       | 4-Aminoquinoline             | Treatment of *Plasmodium falciparum*, optimally in fixed combination with artesunate |
| Piperaquine<sup>1</sup>       | 4-Aminoquinoline             | Treatment of *P. falciparum* in fixed combination with dihydroartemisinin |
| Quinine                       | Quinoline methanol           | Oral and intravenous<sup>1</sup> (for severe infections) treatment of *P. falciparum* |
| Quinidine                     | Quinoline methanol           | Intravenous therapy of severe infections with *P. falciparum*      |
| Mefloquine                    | Quinoline methanol           | Chemoprophylaxis and treatment of infections with *P. falciparum*   |
| Primaquine                    | 8-Aminoquinoline             | Radical cure and terminal prophylaxis of infections with *Plasmodium vivax* and *Plasmodium ovale*; alternative for malaria chemoprophylaxis |
| Sulfadoxine-pyrimethamine     | Folate antagonist combination | Treatment of *P. falciparum*, optimally in combination with artesunate; intermittent preventive therapy |
| Atovaquone-proguanil (Malarone)| Quinone-folate antagonist combination | Treatment and chemoprophylaxis of *P. falciparum* infection |
| Doxycycline                   | Tetracycline                 | Treatment (with quinine) of infections with *P. falciparum*; chemoprophylaxis |
| Halofantrine<sup>1</sup>      | Phenanthrene methanol        | Treatment of infections with some chloroquine-resistant *P. falciparum* |
| Lumefantrine                  | Amyl alcohol                 | Treatment of *P. falciparum* malaria in fixed combination with artemether (Coartem) |
| Artemisinins (Artesunate, artemether, dihydroartemisinin) | Sesquiterpene lactone endoperoxides | Treatment of *P. falciparum* in oral combination regimens for uncomplicated disease and parenterally for severe malaria |

<sup>1</sup>Not available in the United States.

to months if left untreated. *P. malariae* infections need only be treated with chloroquine.

**B. Uncomplicated Falciparum Malaria**

Decisions about how to treat falciparum malaria are affected by the potential for drug resistance, the high cost and limited availability of newer agents for developing world populations, and potential toxicity. The drug sensitivity of individual strains can be determined, but such testing is slow and not useful clinically. Rather, therapeutic decisions are made based on the infecting species and geography. *P. falciparum* is now commonly resistant to chloroquine and sulfadoxine-pyrimethamine in most areas, with the principal exceptions of Central America west of the Panama Canal and Hispaniola. Falciparum malaria from other areas should not be treated with these older drugs, and decisions regarding appropriate chemoprophylaxis should follow the same geographic considerations.

In the developing world, malaria is often treated with suboptimal regimens due to the high cost and limited supplies of newer agents. Chloroquine is still widely used in Africa, and its poor efficacy may be underappreciated due to its antipyretic properties, the ability of some immune individuals to recover from acute malaria without effective therapy, and the fact that recrudescences may not lead to symptoms until weeks after partial effective therapy. Sulfadoxine-pyrimethamine is slower acting than most other agents, and suffers from increasing resistance in most areas. Recommendations for the treatment of uncomplicated falciparum malaria in the developing world have undergone major change in recent years, with artemisinin-based combinations, all including a short-acting artemisinin and longer-acting partner drug, now first-line therapies in nearly all endemic countries. The WHO currently recommends five artemisinin-based combinations to treat falciparum malaria (Table 35–3), but the efficacy of these regimens varies. Other combination therapies are under development. Another drug that remains generally effective for falciparum malaria is quinine, but it must be taken for an extended period to cure disease and is poorly tolerated. Thus, in the developing world, quinine should be reserved for the treatment of severe malaria and for treatment after another regimen has failed (Table 35–4).

In developed countries, malaria is an uncommon but potentially life-threatening infection of travelers and immigrants, many of whom are nonimmune, so they are at risk for rapid progression to severe disease. Nonimmune individuals with falciparum malaria should generally be admitted to the hospital due to risks of rapid progression of disease. Options for the treatment of uncomplicated falciparum malaria in the United States have increased with the approval of artemether-lumefantrine in 2009 (Table 35–4).

**C. Severe Malaria**

Severe malaria is a medical emergency. Parenteral treatment is indicated for severe malaria, as defined above, and with inability to take oral drugs. With appropriate prompt therapy and supportive care, rapid recoveries may be seen in even very ill individuals.

**Table 35–3. WHO recommendations for the treatment of uncomplicated falciparum malaria.**

Standard therapy for severe malaria has been intravenous quinine in most areas and, in the United States, intravenous quinidine, which is equally effective. However, the standard of care is now changing, since intravenous artesunate has shown superiority over quinine.

Patients receiving intravenous quinine or quinidine should receive continuous cardiac monitoring; if QTc prolongation exceeds 25% of baseline, the infusion rate should be reduced. Blood glucose should be monitored every 4–6 hours, and 5–10% dextrose may be coadministered to decrease the likelihood of hypoglycemia. Appropriate care of severe malaria includes maintenance of fluids and electrolytes; respiratory and hemodynamic support; and consideration of blood transfusions, anti-convulsants, antibiotics for bacterial infections, and hemofiltration or hemodialysis. With high parasitemia (> 5–10%), exchange transfusion has been used, but beneficial effects have not clearly been demonstrated, and its role remains uncertain.

Intravenous artesunate has shown superior efficacy and better tolerability than intravenous quinine for severe malaria in large randomized trials in Asian adults and African children. It is the standard of care for severe malaria, although it is not yet available in much of the developing world, where quinine remains standard therapy. In the United States intravenous artesunate is available on an investigational basis through the CDC (for enrollment call 770-488-7788); if approved, the drug is provided emergently from CDC Quarantine Stations. The drug is administered in four doses of 2.4 mg/kg over 3 days, every 12 hours on day 1, and then daily. If artesunate cannot be obtained promptly, severe malaria should be treated with intravenous quinine or quinidine. In endemic regions, if parenteral therapy is not available, intrarectal administration of artemether or artesunate is also effective.

<sup>1</sup>All dosages are oral and refer to salts unless otherwise indicated. See text for additional information on all agents, including toxicities and cautions. See Centers for Disease Control and Prevention’s guidelines (phone: 877-FYI-TRIP; http://www.cdc.gov/malaria/) for additional information and pediatric dosing.

<sup>2</sup>Not available in the United States.

<sup>4</sup>Available in the United States only on an investigational basis through the CDC (phone: 770-488-7788).

<sup>6</sup>Cardiac monitoring should be in place during intravenous administration of quinidine or quinine.

1Avoid loading doses in persons who have received quinine, quinidine, or mefloquine in the prior 24 hours.

<sup>6</sup>With all parenteral regimens, change to an oral regimen as soon as the patient can tolerate it.

G6PD, glucose-6-phosphate dehydrogenase.

D. Antimalarial Drugs

1. Chloroquine—Chloroquine remains the drug of choice for the treatment of sensitive *P falciparum* and other species of malaria parasites (Table 35–4). Chloroquine is active against erythrocytic parasites of all human malaria species. It does not eradicate hepatic stages, so must be used with primaquine to eradicate *P vivax* and *P ovale* infections. Chloroquine-resistant *P falciparum* is widespread in nearly all areas of the world with falciparum malaria, with the exceptions of Central America west of the Panama Canal, Mexico, and Hispaniola. Chloroquine-resistant *P vivax* has been reported from a number of areas, most notably Southeast Asia and Oceania.

Chloroquine is the drug of choice for the treatment of non-falciparum and sensitive falciparum malaria. It rapidly terminates fever (in 24–48 hours) and clears parasitemia (in 48–72 hours) caused by sensitive parasites. Chloroquine is also the preferred chemoprophylactic agent in malarious regions without resistant falciparum malaria.

Eradication of *P vivax* and *P ovale* requires a course of primaquine.

Chloroquine is usually well tolerated, even with prolonged use. Pruritus is common, primarily in Africans. Nausea, vomiting, abdominal pain, headache, anorexia, malaise, blurring of vision, and urticaria are uncommon. Dosing after meals may reduce some adverse events.

2. Amodiaquine and piperaquine—Amodiaquine is a 4-aminoquinoline that is closely related to chloroquine. Amodiaquine has been widely used to treat malaria because of its low cost, limited toxicity and, in some areas,
effectiveness against chloroquine-resistant strains of *P. falciparum*. Use of amodiaquine decreased after recognition of rare but serious side effects, notably agranulocytosis, aplastic anemia, and hepatotoxicity. However, serious side effects are rare with short-term use, and amodiaquine is a component of a new combination therapy (artesunate-amodiaquine) recommended to treat *falciparum* malaria (Table 35–3). Chemoprophylaxis with amodiaquine is best avoided because of increased toxicity with long-term use.

Piperaquine is another 4-aminoquinoline that was previously heavily used in China and has been coformulated with dihydroartemisinin in an artemisinin-based therapy. Piperaquine appears to be well tolerated, to have minimal problems with resistance (despite prior reports of resistance in China), and in combination with dihydroartemisinin to offer a highly efficacious therapy for falciparum malaria.

**3. Mefloquine**—Mefloquine is effective therapy for many chloroquine-resistant strains of *P. falciparum* and against other malarial species. Although toxicity is a concern, mefloquine is also a recommended chemoprophylactic drug. Resistance to mefloquine has been reported sporadically from many areas, but it appears to be uncommon except in regions of Southeast Asia with high rates of multidrug resistance (especially border areas of Thailand).

For treatment of uncomplicated malaria, mefloquine is rapidly active and can be administered as a single dose or in two doses over 1 day. It is used in combination with artesunate in Southeast Asia, where resistance to mefloquine has been seen but the combination remains effective in most areas. It should be taken with meals and swallowed with a large amount of water. Mefloquine is recommended by the CDC for chemoprophylaxis in all malarious areas except those with no chloroquine resistance (where chloroquine is preferred) and some rural areas of Southeast Asia with a high prevalence of mefloquine resistance. Eradication of *P. vivax* and *P. ovale* requires a course of primaquine.

Adverse effects with weekly dosing of mefloquine for chemoprophylaxis include nausea, vomiting, dizziness, sleep and behavioral disturbances, epigastric pain, diarrhea, abdominal pain, headache, rash and, uncommonly, seizures and psychosis. Mefloquine should be avoided in persons with histories of psychiatric disease or seizures.

Adverse effects are more common (up to 50% of treatments) with the higher dosages of mefloquine required for treatment. These effects may be lessened by splitting administration into two doses separated by 6–8 hours. Serious neuropsychiatric toxicities (depression, confusion, acute psychosis, or seizures) have been reported in < 1 in 1000 treatments, but some authorities believe that these are more common. Mefloquine can also alter cardiac conduction, and so it should not be coadministered with quinine, quinidine, or halofantrine, and caution is required if these drugs are used to treat malaria after mefloquine chemoprophylaxis. Mefloquine is generally considered safe in young children and pregnant women.

**4. Quinine and quinidine**—Quinine dihydrochloride and quinidine gluconate remain first-line therapies for falciparum malaria, especially severe disease, although toxicity concerns complicate therapy (Table 35–4). Quinine acts rapidly against the four species of human malaria parasites. Quinidine, the dextrorotatory stereoisomer of quinine, is at least as effective as quinine in the treatment of severe falciparum malaria.

Resistance of *P. falciparum* to quinine is common in some areas of Southeast Asia, where the drug may fail if used alone to treat falciparum malaria. However, quinine still provides at least a partial therapeutic effect in most patients.

Quinine and quinidine are effective treatments for severe falciparum malaria, although intravenous artesunate is becoming the standard of care (see Artemisinins section below). Quinine can be administered slowly intravenously or, in a dilute solution, intramuscularly, but parenteral quinine is not available in the United States, where quinidine is used. The drugs can be administered in divided doses or by continuous intravenous infusion; treatment should begin with a loading dose to rapidly achieve effective plasma concentrations. Intravenous quinine and quinidine should be administered with cardiac monitoring because of their cardiac toxicity and the relative unpredictability of their pharmacokinetics. Therapy should be changed to oral quinine or another agent as soon as the patient has improved and can tolerate oral medications.

In areas without newer combination regimens, oral quinine sulfate is an alternative first-line therapy for uncomplicated falciparum malaria, although poor tolerance may limit compliance. Quinine is commonly used with a second drug (most often doxycycline) to shorten the duration of use (usually to 3 days) and to limit toxicity. Therapeutic dosages of quinine and quinidine commonly cause tinnitus, headache, nausea, dizziness, flushing, and visual disturbances. Hypersensitivity reactions include rash, urticaria, angioedema, and bronchospasm. Hematologic abnormalities include hemolysis (especially with G6PD deficiency), leukopenia, agranulocytosis, and thrombocytopenia. Therapeutic doses may cause hypoglycemia through stimulation of insulin release; this is a particular problem in severe infections and in pregnant patients, who have increased sensitivity to insulin. Overly rapid infusions can cause severe hypotension. ECG abnormalities (QT prolongation) are fairly common, but dangerous arrhythmias are uncommon when the drugs are administered appropriately. Blackwater fever is a rare severe illness, probably due to hypersensitivity, that includes marked hemolysis and hemoglobinuria in the setting of quinine therapy for malaria. Quinine should not be given concurrently with mefloquine and should be used with caution in a patient who has previously received mefloquine. Absorption may be blocked by aluminum-containing antacids. Quinine can raise plasma levels of warfarin and digoxin. Dosage must be reduced in renal insufficiency.

**5. Primaquine**—Primaquine phosphate, a synthetic 8-aminoquinoline, is the drug of choice for the eradication of dormant liver forms of *P. vivax* and *P. ovale* (Table 35–4). It is well absorbed orally, reaching peak plasma levels in 1–2 hours, with a plasma half-life of 3–8 hours. Primaquine is active against hepatic stages of all human malaria
parasites. This action is optimal soon after therapy with chloroquine or quinine. Primaquine also acts against erythrocytic stage parasites, although this activity is too weak for the treatment of active disease, and against gametocytes.

For *P. vivax* and *P. ovale* infections, chloroquine is used to eradicate erythrocytic forms, and if the G6PD level is normal, a 14-day course of primaquine is initiated to eradicate liver hypnozoites and prevent a subsequent relapse. Some strains of *P. vivax*, particularly in New Guinea and Southeast Asia, are relatively resistant to primaquine. For this reason, the CDC doubled the recommended dosage for primaquine to eradicate liver forms (to 52.6 mg primaquine phosphate, or 30 mg base/day) in 2005, but it remains possible that liver forms may not be eradicated by a single treatment.

Standard chemoprophylaxis does not prevent a relapse of *P. vivax* or *P. ovale* infections, since liver hypnozoites are not eradicated by chloroquine or other standard treatments. To diminish the likelihood of relapse, some authorities advocate the use of a treatment course of primaquine after the completion of travel to an endemic area. Primaquine can also be used for chemoprophylaxis to prevent *P. falciparum* and *P. vivax* infection in persons with normal levels of G6PD.

Primaquine in recommended doses is generally well tolerated. It infrequently causes nausea, epigastric pain, abdominal cramps, and headache, especially when taken on an empty stomach. Rare adverse effects include leukopenia, agranulocytosis, leukocytosis, and cardiac arrhythmias. Standard doses of primaquine may cause hemolysis or methemoglobinemia (manifested by cyanosis), especially in persons with G6PD deficiency or other hereditary metabolic defects. Patients should be tested for G6PD deficiency before primaquine is prescribed. When a patient is deficient in G6PD, treatment strategies may consist of (1) withholding therapy and treating subsequent relapses, if they occur, with chloroquine; (2) treating patients with standard dosing, paying close attention to their hematologic status; or (3) treating with weekly primaquine (45 mg base) for 8 weeks. G6PD-deficient individuals of Mediterranean and Asian ancestry are most likely to have severe deficiency, while those of African ancestry usually have a milder biochemical defect. This difference can be taken into consideration in choosing a treatment strategy. Primaquine should be discontinued if there is evidence of hemolysis or anemia and should be avoided in pregnancy.

6. Inhibitors of folate synthesis—Inhibitors of two parasite enzymes involved in folate metabolism, dihydrofolate reductase (DHFR) and dihydropteroate synthase (DHPHS), are used, generally in combination regimens, for the treatment and prevention of malaria, although the drugs are rather slow acting and now limited by resistance.

Fansidar is a fixed combination of sulfadoxine (500 mg) and pyrimethamine (25 mg). The long half-lives of its components allow weekly dosing for chemoprophylaxis, but due to rare serious side effects with long-term dosing, this drug is no longer recommended for this purpose. Sulfadoxine-pyrimethamine became a common back-up drug after chloroquine in Africa, and replaced chloroquine as the first-line therapy in a number of countries. Advantages of sulfadoxine-pyrimethamine include ease of administration (a single oral dose) and low cost. However, resistance to sulfadoxine-pyrimethamine, is now a major problem. In addition, it is not reliably effective in *P. vivax* infections, and its usefulness against *P. ovale* and *P. malariae* infections has not been adequately studied, limiting its utility outside of Africa.

Sulfadoxine-pyrimethamine is a component of two combination regimens for uncomplicated malaria recommended by the WHO (Table 35–3). Sulfadoxine-pyrimethamine plus artesunate has shown efficacy in some areas but is best replaced by more effective combination regimens in most areas. Amodiaquine plus sulfadoxine-pyrimethamine has shown surprisingly good efficacy in many parts of Africa, despite increasing resistance to both components, and probably offers the most practical treatment for uncomplicated malaria in many endemic areas without access to artemisinin-based therapies. Another antifolate combination, trimethoprim-sulfamethoxazole, is widely used to prevent coinfections in patients infected with HIV, and it offers partial protection against malaria. Malarone, a combination of proguanil with atovaquone, is discussed below.

7. Artemisinins—Artemisinin (qinghaosu) is a sesquiterpene lactone endoperoxide, the active component of an herbal medicine that has been used for various indications in China for over 2000 years. Analogs have been synthesized to increase solubility and improve antimalarial efficacy. The most important of these analogs are artesunate, artemether, and dihydroartemisinin. The WHO is encouraging availability of oral artemisinins only in coformulated combination regimens.

Artemisinins act very rapidly against all erythrocytic-stage human malaria parasites. Artemisinin resistance is not yet an important clinical problem, but *P. falciparum* isolates with diminished in vitro susceptibility to artemether have been described, and delayed clearance of parasites has been seen after treatment with artesunate in parts of Southeast Asia.

Artemisinins are playing an increasing role in the treatment of malaria, including multidrug-resistant *P. falciparum* malaria. However, due to their short plasma half-lives, recrudescence rates are unacceptably high after short-course therapy, and they are best used in conjunction with another agent. Also because of their short-half lives, they are not useful in chemoprophylaxis.

Artemisinins should be used for uncomplicated malaria in combination regimens including a longer-acting partner drug, known as artemisinin-based combination therapy. Artesunate plus mefloquine has demonstrated excellent efficacy against multidrug resistant parasites in Thailand, but this regimen is too expensive for widespread use in Africa and other areas. The artemisinin-based combination regimens that are currently most advocated in Africa are artesunate plus amodiaquine (ASAQ) and artemether plus lumefantrine (Coartem), each of which is available as a coformulated product and is the recommended therapy for uncomplicated malaria in a number of countries, although implementation has been slow in some areas. A third available coformulated regimen that has performed well in
clinical trials, and was added to the list of WHO-recommended regimens for uncomplicated falciparum malaria in 2010, is dihydroartemisinin plus piperaquine; this is the first-line regimen in some countries in Southeast Asia. In studies of severe malaria, intramuscular artemether was at least as effective as intramuscular quinine, and intravenous artesunate was superior to intravenous quinine in terms of efficacy and tolerability. Thus, the standard of care for severe malaria is intravenous artesunate, when it is available, although parenteral quinine and quinidine remain acceptable alternatives. Artesunate and artemether have also been effective in the treatment of severe malaria when administered rectally, offering a valuable treatment modality when parenteral therapy is not available.

Artemisinins are very well tolerated. The most commonly reported adverse effects have been nausea, vomiting, and diarrhea, which may often be due to acute malaria, rather than drug toxicity. Neutropenia, anemia, hemolysis, and elevated levels of liver enzymes have been noted rarely. Artemisinins are teratogenic in animals, and they should be avoided in the first trimester of pregnancy for uncomplicated malaria. However, for severe malaria, for which all available treatments entail some risk, the WHO endorses the use of intravenous artesunate or quinine while additional data are gathered on artesunate safety.

8. Atovaquone plus proguanil (Malarone)—Atovaquone, a hydroxynaphthoquinone, is not effective when used alone, due to rapid development of drug resistance. However, Malarone, a fixed combination of atovaquone (250 mg) and the antifolate proguanil (100 mg), is highly effective for both the treatment and chemoprophylaxis of falciparum malaria, and it is approved for both indications in the United States (Table 35–4). It also appears to be active against other species of malaria parasites. Unlike most other antimalarials, Malarone provides activity against both erythrocytic and hepatic stage parasites.

For treatment, Malarone is given at an adult dose of four tablets daily for 3 days. For chemoprophylaxis, Malarone must be taken daily. It has an advantage over mefloquine and doxycycline in requiring shorter durations of treatment before and after the period at risk for malaria transmission, due to activity against liver-stage parasites. It should be taken with food.

Malarone is generally well tolerated. Adverse effects include abdominal pain, nausea, vomiting, diarrhea, headache, and rash, and these are more common with the higher dose required for treatment. Reversible elevations in liver enzymes have been reported. The safety of atovaquone in pregnancy is unknown.

9. Antibiotics—A number of antibacterials in addition to the folate antagonists and sulfonamides are slow-acting antimalarials. None of the antibiotics should be used as single agents for the treatment of malaria due to their slow rate of action. Tetracycline and doxycycline are active against asexual erythrocytic forms of all human malaria parasites. Doxycycline is commonly used in the treatment of falciparum malaria in conjunction with quinidine or quinine, allowing a shorter and better-tolerated course of those drugs (Table 35–4). Doxycycline is also a standard chemoprophylactic drug, especially for use in areas of Southeast Asia with high rates of resistance to other antimalarials, including mefloquine. Doxycycline side effects include gastrointestinal symptoms, candidal vaginitis, and photosensitivity. The drug should be taken while upright with a large amount of water to avoid esophageal irritation. Clindamycin can be used in conjunction with quinine or quinidine in those for whom doxycycline is not recommended, such as children and pregnant women (Table 35–4). The most common toxicities with clindamycin are gastrointestinal. Azithromycin also has antimalarial activity and is now under study for treatment and chemoprophylaxis.

**10. Halofantrine and lumefantrine**—Halofantrine hydrochloride, a phenanthrene-methanol related to quinine, is effective against erythrocytic stages of all four human malaria species. Because of toxicity concerns, it should not be taken with meals. Halofantrine is rapidly effective against most chloroquine-resistant strains of *P. falciparum*, but its use is limited by irregular absorption and cardiac toxicity. As treatment for falciparum malaria, halofantrine is given orally in three 500-mg doses at 6-hour intervals, and this course is repeated in 1 week for nonimmune individuals. Halofantrine is generally well tolerated. The most common adverse effects are abdominal pain, diarrhea, vomiting, cough, rash, headache, pruritus, and elevated liver enzymes. Of greater concern, the drug alters cardiac conduction, with dose-related prolongation of QT and PR intervals. This effect is worsened by prior mefloquine therapy. Rare instances of dangerous arrhythmias and some deaths have been reported. The drug is contraindicated in patients with cardiac conduction defects and should not be used in those who have recently taken mefloquine. It is also contraindicated in pregnancy.

Lumefantrine, an aryl alcohol related to halofantrine, is available only as a fixed-dose combination with artemether (Coartem or Riamet). As with halofantrine, oral absorption is highly variable. It is improved when the drug is taken with food. Use of Coartem with a fatty meal is recommended. Coartem is highly effective for the treatment of falciparum malaria, but it is fairly expensive and requires twice-daily dosing. Despite these limitations, due to its reliable efficacy against falciparum malaria, Coartem is the first-line therapy for malaria in many malarious countries. Coartem is well tolerated; side effects include headache, dizziness, loss of appetite, gastrointestinal symptoms, and palpitations. Importantly, Coartem does not appear to cause the cardiac toxicity seen with halofantrine.

**Prevention**

Malaria is transmitted by night-biting anopheline mosquitoes. Bed nets, in particular nets treated with permethrin insecticides, are heavily promoted as inexpensive means of antimalarial protection, and improvement in mortality rates has been demonstrated. Extensive efforts are also underway to develop a malaria vaccine, and partial
protection of African children has been demonstrated, but a vaccine offering complete protection is not anticipated in the near future. The availability of improved modalities to control mosquito vectors and treat and prevent malaria has heightened enthusiasm for malaria elimination, and there have been important gains in some areas; however, control remains very challenging in highly endemic regions, and elimination is not expected in these areas in the foreseeable future.

When travelers from nonendemic to endemic countries are counseled on the prevention of malaria, it is imperative to emphasize measures to prevent mosquito bites (insect repellents, insecticides, and bed nets), since parasites are increasingly resistant to multiple drugs and no chemoprophylactic regimen is fully protective. Chemoprophylaxis is recommended for all travelers from nonendemic regions to endemic areas, although risks vary greatly for different locations, and some tropical areas entail no risk; specific recommendations for travel to different locales are available from the CDC (www.cdc.gov). Current recommendations from the CDC include the use of chloroquine for chemoprophylaxis in the few areas with only chloroquine-sensitive malaria parasites (principally the Caribbean and Central America west of the Panama Canal), mefloquine or Malarone for most other malarious areas, and doxycycline for areas with a high prevalence of multidrug-resistant falciparum malaria (principally parts of Southeast Asia) (Table 35–5). Recommendations should be checked regularly (Phone: 877-FYI-TRIP; Internet: http://wwwnc.cdc.gov/travel/) because they may change in response to changing resistance patterns and increasing experience with new drugs. In some circumstances, it may be appropriate for travelers to not use chemoprophylaxis but to carry supplies of drugs with them in case a febrile illness develops and medical attention is unavailable. Regimens for self-treatment include artemisinin-based combinations, Malarone, and quinine. Most authorities do not recommend routine terminal chemoprophylaxis with primaquine to eradicate dormant hepatic stages of *P. vivax* and *P. ovale* after travel, but this may be appropriate in some circumstances, especially for travelers with major exposure to these parasites.

Regular chemoprophylaxis is not a standard management practice in developing world populations due to the expense and potential toxicities of long-term therapy. However, there is increasing interest in intermittent preventive therapy, whereby at-risk populations, in particular pregnant women and children, receive antimalarial therapy at set intervals. This strategy may decrease the incidence of malaria while allowing antimalarial immunity to develop. Intermittent preventive therapy has been best studied with sulfadoxine-pyrimethamine, a long-acting drug that is administered in a single dose. During pregnancy, sulfadoxine-pyrimethamine provided once during both the second and third trimesters has improved pregnancy outcomes. In infants, therapy with sulfadoxine-pyrimethamine following standard immunization schedules has offered benefits. With increasing resistance, it is not clear if sulfadoxine-pyrimethamine will retain prophylactic efficacy or if other drugs with shorter half-lives will be effective.

### Prognosis

When treated appropriately, uncomplicated malaria generally responds well, with resolution of fevers within 1–2 days and a mortality of about 0.1%. Severe malaria can commonly progress to death, but many children respond well to therapy. In the developed world, mortality from malaria is mostly in adults, and often follows extended illnesses and secondary complications long after eradication of the malarial infection. Pregnant women are at particular risk.

---

*1Recommendations may change, as resistance to all available drugs is increasing. See text for additional information on toxicities and cautions. For additional details and pediatric dosing, see Centers for Disease Control and Prevention’s guidelines (phone: 800-CDC-INFO, http://wwwnc.cdc.gov/travel/). Travelers to remote areas should consider carrying effective therapy (see text) for use if a febrile illness develops, and they cannot reach medical attention quickly.*

*2Areas without known chloroquine-resistant *P. falciparum* are Central America west of the Panama Canal, Haiti, Dominican Republic, Egypt, and most malarious countries of the Middle East. Malarone or mefloquine is currently recommended for other malarious areas except for border areas of Thailand, where doxycycline is recommended.

*3For drugs other than primaquine, begin 1–2 weeks before departure (except 2 days before for doxycycline and Malarone) and continue for 4 weeks after leaving the endemic area (except 1 week for Malarone). All dosages refer to salts unless otherwise indicated.*

*4Screen for glucose-6-phosphate dehydrogenase deficiency before using primaquine.*

during their first pregnancy, probably due to the selection of *P. falciparum* strains that preferentially sequester in the placenta; multiparous women are more likely to have antibodies against these strains and thus avoid severe disease. Malaria in pregnancy also increases the likelihood of poor pregnancy outcomes, with increased prematurity, low birth weight, and mortality.

### When to Refer

Referral to an expert on infectious diseases or travel medicine is important with all cases of malaria in the United States, and in particular for *falciparum* malaria, as management can be complex, but referral should not lead to a delay in initial diagnosis and therapy, since delays in therapy can lead to severe illness or death.

### When to Admit

- Non-*falciparum* malaria generally does not cause severe disease and responds well to therapy, and so admission is only warranted if a patient presents with specific problems that require hospital management.
- Patients with *falciparum* malaria are generally admitted because the disease can progress rapidly to severe illness; exceptions may be made with individuals who are from malaria-endemic areas, and thus expected to have a degree of immunity, who are without evidence of severe disease, and who are judged able to return promptly for medical attention if their disease progresses.

---

**Babesiosis**

Babesiosis is an uncommon intraerythrocytic infection caused mainly by two *Babesia* species and transmitted by *Ixodes* ticks. In Europe, where only a few dozen cases of babesiosis have been reported, infection is caused by *Babesia divergens*, which also infects cattle. In the United States, hundreds of cases of babesiosis have been reported, and infection is caused by *Babesia microti*, which also infects wild mammals. Most babesiosis in the United States occurs in the coastal northeast, with some cases also in the upper midwest, following the geographic range of the vector *Ixodes scapularis*, and Lyme disease and anaplasmosis, which are spread by the same vector. The incidence of the disease appears to be increasing in some areas. Rare episodes of illnesses caused by *B microti*, *B divergens*, and other Babesia-like organisms have been reported from other areas. Babesiosis can also be transmitted by blood transfusion.

#### General Considerations

With *B microti* infections, symptoms appear 1 to several weeks after a tick bite; parasitemia is evident after 2–4 weeks. Patients usually do not recall the tick bite. The typical flu-like illness develops gradually and is characterized by fever, fatigue, headache, arthralgia, and myalgia. Other findings may include nausea, vomiting, abdominal pain, sore throat, depression, emotional lability, anemia, thrombocytopenia, and splenomegaly. Parasitemia may continue for months to years, with or without symptoms, and the disease is usually self-limited. Severe complications are most likely to occur in older persons or in those who have had splenectomy. Serious complications include respiratory failure, hemolytic anemia, disseminated intravascular coagulation, congestive heart failure, and acute kidney injury. In a study of hospitalized patients, the mortality rate

---

**ESSENTIALS OF DIAGNOSIS**

- History of tick bite or exposure to ticks.
- Fever, flu-like symptoms, anemia.
- Intraerythrocytic parasites on Giemsa-stained blood smears.
- Positive serologic tests.

---

**A. Symptoms and Signs**

With *B microti* infections, symptoms appear 1 to several weeks after a tick bite; parasitemia is evident after 2–4 weeks. Patients usually do not recall the tick bite. The typical flu-like illness develops gradually and is characterized by fever, fatigue, headache, arthralgia, and myalgia. Other findings may include nausea, vomiting, abdominal pain, sore throat, depression, emotional lability, anemia, thrombocytopenia, and splenomegaly. Severe complications are most likely to occur in older persons or in those who have had splenectomy. Serious complications include respiratory failure, hemolytic anemia, disseminated intravascular coagulation, congestive heart failure, and acute kidney injury. In a study of hospitalized patients, the mortality rate
TOXOPLASMOSIS

ESSENTIALS OF DIAGNOSIS

- Infection confirmed by isolation of *Toxoplasma gondii* or identification of tachyzoites in tissue or body fluids.
- **Primary infection**
  - Fever, malaise, headache, sore throat.
  - Lymphadenopathy.
  - Positive IgG and IgM serologic tests.
- **Congenital infection**
  - Follows acute infection of seronegative mothers and leads to CNS abnormalities and retinochoroiditis.
  - Infection in immunocompromised persons
  - Reactivation leads to encephalitis, retinochoroiditis, pneumonitis, myocarditis.
  - Positive IgG but negative IgM serologic tests.

General Considerations

*T. gondii*, an obligate intracellular protozoan, is found worldwide in humans and in many species of mammals and birds. The definitive hosts are cats. Humans are infected after ingestion of cysts in raw or undercooked meat, ingestion of oocysts in food or water contaminated by cats, transplacental transmission of trophozoites or, rarely, direct inoculation of trophozoites via blood transfusion or organ transplantation. *Toxoplasma* seroprevalence varies widely. It has decreased in the United States to about 20–30%, but it is much higher in other countries in both the developed and developing worlds, where it may exceed 80%.

Clinical Findings

A. Symptoms and Signs

The clinical manifestations of toxoplasmosis may be grouped into four syndromes.

1. **Primary infection in the immunocompetent person**
   - After ingestion, *T. gondii* infection progresses from the gastrointestinal tract to lymphatics, and then dissemination. Most acute infections are asymptomatic. About 10–20% are symptomatic after an incubation period of 1–2 weeks. Acute infections in immunocompetent persons typically present as mild, febrile illnesses that resemble infectious mononucleosis. Nontender cervical or diffuse lymphadenopathy may persist for weeks to months. Systemic findings may include fever, malaise, headache, sore throat, rash, myalgias, hepatosplenomegaly, and atypical lymphocytosis. Rare severe manifestations are pneumonitis, meningoencephalitis, hepatitis, myocarditis, polymyositis, and retinochoroiditis. Symptoms may fluctuate, but most patients recover spontaneously within at most a few months.
2. Congenital infection—Congenital transmission occurs as a result of infection, which may be symptomatic or asymptomatic, in a nonimmune woman during pregnancy. Fetal infection follows maternal infection in 30–50% of cases, but this risk varies by trimester: 10–25% during the first, 30–50% during the second, and 60% or higher during the third trimester. In the United States, an estimated 400 to 4000 congenital infections occur yearly. While the risk of fetal infection increases, the risk of severe fetal disease decreases over the course of pregnancy. Early fetal infections commonly lead to spontaneous abortion, stillbirths, or severe neonatal disease, including neurologic manifestations. Neurologic findings can include seizures, psychomotor retardation, deafness, and hydrocephalus. Retinochoroiditis and other sight-threatening eye lesions may develop. Systemic findings include fever or hypothermia, jaundice, vomiting, diarrhea, hepatosplenomegaly, pneumonitis, myocarditis, and rash. Infections later in pregnancy less commonly lead to major fetal problems. Most infants appear normal at birth, but they may have subtle abnormalities and progress to symptoms and signs of congenital toxoplasmosis later in life. Hepatosplenomegaly and lymphadenopathy may develop in the first few months of life; CNS and eye disease often present later. The most common late presentation of congenital toxoplasmosis is retinochoroiditis.

3. Retinochoroiditis—This manifestation of congenital toxoplasmosis presents weeks to years after congenital infection, commonly in teenagers or young adults. Retinochoroiditis also is seen in persons who acquire infection early in life, and these patients more often present with unilateral disease. Uveitis is also seen. Disease presents with pain, photophobia, and visual changes, usually without systemic symptoms. Signs and symptoms eventually improve, but visual defects may persist. Rarely, progression may result in glaucoma and blindness.

4. Disease in the immunocompromised person—Reactivated toxoplasmosis occurs in patients with AIDS, cancer, or those given immunosuppressive drugs. In patients with advanced AIDS, the most common manifestation is encephalitis, with multiple necrotizing brain lesions. The encephalitis usually presents subacutely, with fever, headache, altered mental status, focal neurologic findings, and other evidence of brain lesions. Less common manifestations of toxoplasmosis in patients with AIDS are chorioretinitis and pneumonitis. Chorioretinitis presents with ocular pain and alterations in vision. Pneumonitis presents with fever, cough, and dyspnea. Toxoplasmosis can develop in seronegative recipients of solid organ or bone marrow transplants due to reactivation or, more rarely, transmission of infection. Reactivation also can occur in those with hematologic malignancies or treated with immunosuppressive drugs. With primary or reactivated disease in those with immunodeficiency due to malignancy or immunosuppressive drugs, toxoplasmosis is similar to that in individuals with AIDS, but pneumonitis and myocarditis are more common.

B. Diagnostic Testing

1. Identification of parasites—Organisms can be seen in tissue or body fluids, although they may be difficult to identify; special staining techniques can facilitate identification. The demonstration of tachyzoites indicates acute infection; cysts may represent either acute or chronic infection. With lymphadenopathy due to toxoplasmosis, examination of lymph nodes usually does not show organisms. Parasite identification can also be made by inoculation of tissue culture or mice. PCR can be used for sensitive identification of organisms in amniotic fluid, blood, CSF, aqueous humor, and bronchoalveolar lavage fluid.

2. Serologic diagnosis—Multiple serologic methods are used, including the Sabin-Feldman dye test, enzyme-linked immunosorbent assay (ELISA), indirect fluorescent antibody test, and agglutination tests. IgG antibodies are seen within 1–2 weeks of infection, and usually persist for life. IgM antibodies peak earlier than IgG and decline more rapidly, although they may persist for years. In immunocompromised individuals in whom reactivation is suspected, a positive IgG assay indicates distant infection, and thus the potential for reactivated disease; a negative IgG argues strongly against reactivation toxoplasmosis. With reactivation in immunocompromised persons, IgM tests are generally negative.

3. During pregnancy and in newborns—Conversion from a negative to positive serologic test or rising titers are suggestive of acute infection, but tests are not routinely performed during pregnancy. When pregnant women are screened, negative IgG and IgM assays exclude active infection, but indicate the risk of infection during the pregnancy. The pattern of positive IgG with negative IgM is highly suggestive of chronic infection, with no risk of congenital disease unless the mother is severely immunocompromised. A positive IgM test is concerning for new infection because of the risk of congenital disease. Confirmatory testing should be performed before consideration of treatment or possible termination of pregnancy due to the limitations of available tests. Tests of the avidity of anti-IgG antibodies can be helpful, but a battery of tests is needed for confirmation of acute infection during pregnancy. When acute infection during pregnancy is suspected, PCR of amniotic fluid offers a sensitive assessment for congenital disease; this test should optimally be performed at 18 weeks of gestation. In newborns, positive IgM or IgA antibody tests are indicative of congenital infection, although the diagnosis is not ruled out by a negative test. Positive IgG assays may represent transfer of maternal antibodies without infection of the infant. Organisms may be identified by PCR; smears; or culture of blood, CSF, or tissue.

4. In immunocompetent individuals—Individuals with a suggestive clinical syndrome should be tested for IgG and IgM antibodies. Seroconversion, a 16-fold rise in antibody titer, or an IgM titer > 1:64 are suggestive of acute infection, although false-positive results may occur. Acute infection can also be diagnosed by detection of tachyzoites in tissue, culture of organisms, or PCR of blood or body
fluids. Histologic evaluation of lymph nodes can show characteristic morphology, with or without organisms.

5. In immunodeficient individuals—A presentation consistent with toxoplasmic encephalitis warrants imaging of the brain. CT and MRI scans typically show multiple ring-enhancing cerebral lesions, most commonly involving the corticomedullary junction and basal ganglia. MRI is the more sensitive imaging modality. In AIDS patients with a positive IgG serologic test and no recent antitoxoplasma or antiviral therapy, the predictive value of a typical imaging study is about 80%. The other common diagnosis in this setting is CNS lymphoma, which more typically causes a single brain lesion. The differential diagnosis also includes tuberculosis, bacterial brain abscess, fungal abscess, and carcinoma. Diagnosis of CNS toxoplasmosis is most typically made after a therapeutic trial, with clinical and radiologic improvement expected within 2–3 weeks. Definitive diagnosis requires brain biopsy and search for organisms and typical histology. In retinochoroiditis, funduscopic examination shows vitreous inflammatory reaction, white retinal lesions, and pigmented scars. Diagnosis of other clinical entities in immunocompromised individuals is generally based on histology.

Treatment

A. Approach to Treatment

Therapy is generally not necessary in immunocompetent persons, since primary illness is self-limited. However, for severe, persistent, or visceral disease, treatment for 2–4 weeks may be considered. Treatment is appropriate for primary infection during pregnancy because the risk of fetal transmission or the severity of congenital disease may be reduced. For retinochoroiditis, most episodes are self-limited, and opinions vary on indications for treatment. Treatment is often advocated for episodes with decreases in visual acuity, multiple or large lesions, macular lesions, significant inflammation, or persistence for over a month. Immunocompromised patients with active infection must be treated. For those with transient immunodeficiency, therapy can be continued for 4–6 weeks after cessation of symptoms. For those with persistent immunodeficiency, such as AIDS patients, full therapy for 4–6 weeks is followed by maintenance therapy with lower doses of drugs. Immunodeficient patients who are asymptomatic but have a positive IgG serologic test should receive long-term chemoprophylaxis.

B. Medications

Drugs for toxoplasmosis are active only against tachyzoites, so they do not eradicate infection. Standard therapy is the combination of pyrimethamine (200 mg loading dose, then 50–75 mg [1 mg/kg] orally once daily) plus sulfadiazine (1–1.5 g orally four times daily), with folinic acid (10–20 mg orally once daily) to prevent bone marrow suppression. Patients should be screened for a history of sulfonamide sensitivity (skin rashes, gastrointestinal symptoms, hepatotoxicity). To prevent crystal-induced nephrotoxicity, good urinary output should be maintained. Pyrimethamine side effects include headache and gastrointestinal symptoms. Even with folic acid therapy, bone marrow suppression may occur; platelet and white blood cell counts should be monitored at least weekly. A first-line alternative to sulfadiazine is clindamycin (600 mg orally four times daily). Other possible alternatives are trimethoprim-sulfamethoxazole or combining pyrimethamine with atovaquone, clarithromycin, azithromycin, or dapsone. Pyrimethamine is not used during the first trimester of pregnancy due to its teratogenicity. Standard therapy for the treatment of acute toxoplasmosis during pregnancy is with spiramycin (1 g orally three times daily until delivery). This therapy is used only to decrease the risk of fetal infection; it reduces the frequency of transmission to the fetus by about 60%. Spiramycin does not cross the placenta, so when fetal infection is documented or for acute infections late in pregnancy (which commonly lead to fetal transmission) treatment with combination regimens as described above is indicated.

Prevention

Prevention of primary infection centers on avoidance of undercooked meat or contact with material contaminated by cat feces, particularly for seronegative pregnant women and immunocompromised persons. For meat, irradiation, cooking to 66°C, or freezing to –20°C kills tissue cysts. Thorough cleaning of hands and surfaces is needed after contact with raw meat or areas contaminated by cats. Oocysts passed in cat feces can remain infective for a year or more, but fresh oocysts are not infective for 48 hours. For best protection, litter boxes should be changed daily and soaked in boiling water for 5 minutes. In addition, gloves should be worn when gardening, fruits and vegetables should be thoroughly washed, and ingestion of dried meat should be avoided.

Universal screening of pregnant women for *T gondii* antibodies is conducted in some countries but not the United States. Pregnant women should ideally have their serum examined for IgG and IgM antibody, and those with negative titers should adhere to the prevention measures described above. Seronegative women who continue to have environmental exposure should undergo repeat serologic screening several times during pregnancy.

For immunocompromised individuals, chemoprophylaxis to prevent primary or reactivated infection is warranted. For transplant recipients, pyrimethamine (25 mg daily orally for 6 weeks) has been used. For advanced AIDS patients and others, chemoprophylaxis with trimethoprim-sulfamethoxazole (one double-strength tablet daily or two tablets three times weekly), used primarily for protection against *Pneumocystis*, is also effective against *T gondii*. Alternatives are pyrimethamine plus either sulfadoxine or dapsone (various regimens). In AIDS patients, chemoprophylaxis can be discontinued if antiretroviral therapy leads to immune reconstitution.

Entamoeba histolytica is unknown. Mortality from invasive and extraintestinal disease, most commonly liver abscess.

Disease follows penetration of the intestinal wall, resulting in diarrhea, and with severe involvement, dysentery and abdominal pain. With dysentery, physical findings include high fevers, prostration, vomiting, abdominal pain and tenderness, hepatic enlargement, and hypotension. Severe presentations are more common in young children, pregnant women, those who are malnourished, and those receiving corticosteroids. Thus, in endemic regions, corticosteroids should not be started for presumed inflammatory bowel disease without first ruling out amebiasis. Fulminant amebic colitis can progress to necrotizing colitis, intestinal perforation, mucosal sloughing, and severe hemorrhage, with mortality rates over 40%. More chronic complications of intestinal amebiasis include chronic diarrhea with weight loss, which may last for months to years; bowel ulcerations; and amebic appendicitis. Localized granulomatous lesions (amebomas) can present after either dysentery or chronic intestinal infection. Clinical findings include pain, obstructive symptoms, and hemorrhage and may suggest intestinal carcinoma.

2. Extraintestinal amebiasis—The most common extraintestinal manifestation is amebic liver abscess. This can occur with colitis, but more frequently presents without history of prior intestinal symptoms. Patients present with the acute or gradual onset of abdominal pain, fever, an enlarged and tender liver, anorexia, and weight loss. Diarrhea is present in a small number of patients. Physical examination may show intercostal tenderness. Abscesses are most commonly single and in the right lobe of the liver, and they are much more common in men. Without prompt treatment, amebic abscesses may rupture into the pleural, peritoneal, or pericardial space, which is often fatal. Amebic infections may rarely occur throughout the body, including the lungs, brain, and genitourinary system.

B. Laboratory Findings

Laboratory studies with intestinal amebiasis show leukocytosis and hematochezia, with fecal leukocytes not present in all cases. With extraintestinal amebiasis, leukocytosis and elevated liver function studies are seen.

C. Diagnostic Testing

Diagnosis is by finding E histolytica or its antigen or by serologic tests. However, each method has limitations.

1. Intestinal amebiasis—Diagnosis is most commonly made by identifying organisms in the stool. E histolytica and E dispar cannot be distinguished, but the identification of amebic trophozoites or cysts in a symptomatic patient is highly suggestive of amebiasis. Stool evaluation for organisms is not highly sensitive (~30–50% for amebic colitis), and at least three stool specimens should be evaluated after concentration and staining. Multiple serologic assays are available; these tests are fairly sensitive, although sensitivity is lower (~70% in colitis) early in illness, and they cannot distinguish recent and old disease, as they remain positive.
Treatment of amebiasis generally entails the use of metronidazole or tinidazole plus a luminal agent (Table 35–6). Effective luminal agents are diloxanide furoate (500 mg orally three times daily with meals for 10 days), iodoquinol (diiodohydroxyquin; 650 mg orally three times daily for 21 days), and paromomycin (30 mg/kg base orally, maximum 3 g, in three divided doses after meals daily for 7 days). Side effects associated with luminal agents are flatulence with diloxanide furoate, mild diarrhea with iodoquinol, and gastrointestinal symptoms with paromomycin. Relative contraindications are thyroid disease for iodoquinol and kidney disease for iodoquinol or paromomycin.

Treatment of intestinal amebiasis requires metronidazole (750 mg orally three times daily for 10 days) or tinidazole (2 g orally once daily for 3 days for mild disease and 5 days for serious disease) plus a luminal agent (Table 35–6). Metronidazole has most commonly been used in the United States, but tinidazole offers simpler dosing and less side effects. Metronidazole often induces transient nausea, vomiting, epigastric discomfort, headache, or a metallic taste. A disulfiram-like reaction may occur if alcohol is coingested. Metronidazole should be avoided in pregnant or nursing mothers if possible. The same toxicities and concerns probably apply for tinidazole, although it appears to be better tolerated. Fluid and electrolyte replacement is also important for patients with significant diarrhea. Surgical management of acute complications of intestinal amebiasis is best avoided whenever possible. Successful therapy of severe amebic colitis may be followed by postdysenteric colitis, with continued diarrhea without persistent infection; this syndrome generally resolves in weeks to months.

Alternatives for the treatment of intestinal amebiasis are tetracycline (250–500 mg orally four times daily for 10 days) plus chloroquine (500 mg orally daily for 7 days). Emetine or dehydroemetine, which are not available in the United States, can be given subcutaneously (preferred) or intravenously in a dose of 1–1.5 mg/kg/d; the maximum daily dose is 90 mg for dehydroemetine and 65 mg for emetine). These agents are effective but cardiotoxic with a narrow therapeutic range and should be used only until severe disease is controlled. They cause nausea, vomiting, and pain at the injection site.

Amebic liver abscess is also treated with metronidazole or tinidazole plus a luminal agent (even if intestinal infection is not documented; Table 35–6). Metronidazole can be used intravenously when necessary. With failure of initial response to metronidazole or tinidazole, chloroquine, emetine or dehydroemetine may be added. Needle aspiration may be helpful for large abscesses (over 5–10 cm), in particular if the diagnosis remains uncertain, if there is an initial lack of response, or if a patient is very ill, suggesting imminent abscess rupture. With successful therapy, abscesses disappear slowly (over months).

**Prevention & Control**

Prevention requires safe water supplies; sanitary disposal of human feces; adequate cooking of food; protection of food sources; hygienic practices; and eradication of the reservoir host. Asymptomatic infection with _E dispar_ does not require therapy. This organism cannot be differentiated morphologically from _E histolytica_, but with negative serology _E dispar_ colonization is likely, and treatment is not indicated. Colonization with _E histolytica_ is generally treated with a luminal agent. Effective luminal agents are diloxanide furoate (500 mg orally three times daily with meals for 10 days), iodoquinol (diiodohydroxyquin; 650 mg orally three times daily for 21 days), and paromomycin (30 mg/kg base orally, maximum 3 g, in three divided doses after meals daily for 7 days). Side effects associated with luminal agents are flatulence with diloxanide furoate, mild diarrhea with iodoquinol, and gastrointestinal symptoms with paromomycin. Relative contraindications are thyroid disease for iodoquinol and kidney disease for iodoquinol or paromomycin.\[Figure 35–7. Gross pathology showing intestinal ulcers due to amebiasis. (Courtesy of Dr. Mae Melvin, Public Health Image Library, CDC.)\]
The free-living amebas that cause disease in humans are of the genera *Acanthamoeba, Naegleria, Balamuthia,* and *Sappinia.* The organisms are widely distributed in soil and fresh and brackish water. *Acanthamoeba* and *Naegleria* species have been found to harbor *Legionella,* *Vibrio cholerae,* and other endosymbiotic bacteria and may serve as a reservoir for these organisms.

### 1. Primary Amebic Meningoencephalitis

Primary amebic meningoencephalitis is a fulminating, hemorrhagic, necrotizing meningoencephalitis that occurs in healthy children and young adults and is rapidly fatal. It is caused by free-living amebas, most commonly *Naegleria fowleri,* but also *Balamuthia mandrillaris* and *Acanthamoeba* species. *N. fowleri* is a thermophilic organism found in fresh and polluted warm lake water, domestic water supplies, swimming pools, thermal water, and sewers. Most patients give a history of exposure to warm fresh water. The incubation period varies from 2 to 15 days. Early symptoms include headache, fever, stiff neck, and lethargy, often associated with rhinitis and pharyngitis. Vomiting, disorientation, and other signs of meningoencephalitis develop within 1 or 2 days, followed by coma and then death within 7–10 days. No distinctive clinical features distinguish the infection from acute bacterial meningoencephalitis. CSF shows hundreds to thousands of leukocytes and erythrocytes per cubic millimeter. Protein is usually elevated, and

### INFECTIONS WITH PATHOGENIC FREE-LIVING AMEBAS

#### ESSENTIALS OF DIAGNOSIS

- Acute meningoencephalitis or chronic granulomatous encephalitis after contact with warm fresh water.
- Keratitis, particularly in contact lens users.

References:
glucose is normal or moderately reduced. A fresh wet mount of the CSF may show motile trophozoites. Staining with Giemsa or Wright stain will identify the trophozoites. Species identification is based on morphology and immunologic methods. Primary amebic meningoencephalitis is nearly always fatal. Amphotericin B appears to be the drug of choice; one survivor was treated with intravenous and intraheathal amphotericin B, intravenous miconazole, and oral rifampin.

**2. Granulomatous Amebic Encephalitis**

*Acanthamoeba* species and *B. mandrillaris* can cause an encephalitis that is more chronic in nature than primary amebic meningoencephalitis. One case of encephalitis caused by *Sappinia* has also been described. Neurologic disease may be preceded by skin lesions, including ulcers and nodules. After an uncertain incubation period neurologic symptoms develop slowly, with headache, meningismus, nausea, vomiting, lethargy, and low-grade fevers progressing over weeks to months to focal neurologic findings, mental status abnormalities, and eventually coma and death. CT and MRI show single or multiple nonspecific lesions. Lumbar puncture is dangerous due to increased intracranial pressure. CSF shows a lymphocytic pleocytosis with elevated protein; amebas are not typically seen. Diagnosis can be made by biopsy of skin or brain lesions. Information on the treatment of granulomatous amebic encephalitis is limited. Some patients have been successfully treated with various combinations of flucytosine, pentamidine, fluconazole or itraconazole, sulfadiazine, trimetoprim-sulfamethoxazole, and azithromycin.

**3. Acanthamoeba Keratitis**

Acanthamoeba keratitis is a painful, sight-threatening corneal infection. It is associated with corneal trauma, most commonly after use of contact lenses and contaminated saline solution. Symptoms include sudden eye pain, photophobia, tearing, and blurred vision. The keratitis progresses slowly, with waxing and waning clinical findings over months, and can progress to blindness. Lack of response to antibacterial, antifungal, and antiviral topical treatments and potential use of contaminated contact lens solution are suggestive of the diagnosis. Ocular examination shows corneal ring infiltrates, but these can also be caused by other pathogens. The diagnosis can be made by examination or culture of corneal scrapings. Available diagnostic techniques include examination of a wet preparation for cysts and motile trophozoites, examination of stained specimens, evaluation with immunofluorescent reagents, culture of organisms, and PCR.

Acanthamoeba keratitis can be cured with local therapy. Topical propamidine isethionate (0.1%), chlorhexidine digluconate (0.02%), polyhexamethylene biguanide, neomycin-polymyxin B-gramicidin, miconazole, and combinations of these agents have been used successfully. Oral itraconazole or ketoconazole can be added for deep keratitis. Drug resistance has been reported. Use of corticosteroid therapy is controversial. In some cases, debridement and penetrating keratoplasty have been performed in addition to medical therapy. Corneal grafting can be done after the amebic infection has been eradicated.

---

**COCCIDIOSIS (Cryptosporidiosis, Isosporiasis, Cyclosporiasis, Sarcocystosis) & MICROSPORIDIOSIS**

**ESSENTIALS OF DIAGNOSIS**

- Acute diarrhea, especially in children in developing countries.
- Outbreaks of diarrhea secondary to contaminated water or food.
- Prolonged diarrhea in immunocompromised persons.
- Diagnosis mostly by identifying organisms in specially stained stool specimens.

**General Considerations**

The causes of coccidiosis are *Cryptosporidium* species (*C. parvum, C. hominis, and others*); *Isospora belli*; *Cyclospora cayetanensis*; and *Sarcocystis* species. Microsporidiosis is caused by at least 14 species, most commonly *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*. These infections occur worldwide, particularly in the tropics and in regions where hygiene is poor. They are causes of endemic childhood gastroenteritis (particularly in malnourished children in developing countries); institutional and community outbreaks of diarrhea; traveler’s diarrhea; and acute and chronic diarrhea in immunosuppressed patients, in particular those with AIDS. They are all notable for the potential to cause prolonged diarrhea, often lasting for a number of weeks. Clustering occurs in households, day care centers, and among sexual partners.

The infectious agents are oocysts (coccidiosis) or spores (microsporidiosis) transmitted from person to person or by contaminated drinking or swimming water or food. Ingested oocysts release sporozoites that invade and multiply in enterocytes, primarily in the small bowel. Coccidian oocysts and microsporidian cysts can remain viable in the environment for years.

*I. belli* and *C. cayetanensis* appear to infect only humans. *C. cayetanensis* has caused a number of food-borne outbreaks in the United States in recent years, most commonly
associated with imported fresh produce. *Sarcocystis* infects many species; humans are intermediate hosts (infected by ingestion of fecal sporocysts) for some species but definitive hosts for *Sarcocystis bovihominis* and *Sarcocystis suihominis* (infected by ingestion of tissue cysts in undercooked beef and pork, respectively).

Cryptosporidiosis is a zoonosis (*C. parvum* principally infects cattle), but most human infections are acquired from humans, in particular with *C. hominis*. Cryptosporidia are highly infectious and readily transmitted in day care settings and households. They have caused large community outbreaks due to contaminated water supplies (causing ~400,000 illnesses in Milwaukee in 1993) and are the leading cause of recreational water–associated outbreaks of gastroenteritis. Of note, coccidia and microsporidians will generally be missed on routine evaluations of stool for ova and parasites, as they require special staining techniques for identification.

#### Clinical Findings

**A. Symptoms and Signs**

1. **Cryptosporidiosis**—The incubation period appears to be about 1–14 days. In developing countries, disease is seen primarily in children under 5 years of age, where cryptosporidiosis causes 5–10% of cases of childhood diarrhea. Presenting symptoms in children include acute watery diarrhea, abdominal pain, and cramps, with rapid resolution in most patients; however, symptoms quite commonly persist for 2 weeks or more. In developed countries, most patients are adults. Diarrhea in immunocompetent individuals typically lasts from 5 to 10 days. It is usually watery, with accompanying abdominal pain and cramps, nausea, vomiting, and fever. Relapses may follow initial resolution of symptoms. Mild illness and asymptomatic infection may also be common.

   Cryptosporidiosis is a well-characterized cause of diarrhea in those with AIDS. It was common in this population before the advent of highly active antiretroviral therapy, particularly in those with advanced immunosuppression. Clinical manifestations are variable, but patients commonly have chronic diarrhea with frequent foul smelling stools, malabsorption, and weight loss. Severe, life-threatening watery diarrhea may be seen. Cryptosporidiosis also causes extraintestinal disease with AIDS, including pulmonary infiltrates with dyspnea and biliary tract infection with sclerosing cholangitis and AIDS cholangiopathy.

2. **Isosporiasis**—The incubation period for *I. belli* is about 1 week. In immunocompetent persons, it usually causes a self-limited watery diarrhea lasting 2–3 weeks, with abdominal cramps, anorexia, malaise, and weight loss. Fever is unusual. Chronic symptoms may persist for months in some patients. In immunocompromised patients, isosporiasis more commonly causes severe and chronic diarrhea, with complications including marked dehydration, malnutrition, and hemorrhagic colitis. Extraintestinal disease has been reported rarely.

3. **Cyclosporiasis**—*C. cayetanensis* oocysts must undergo a period of sporulation of 7 days or more after shedding before they become infectious. Therefore, person-to-person spread is unlikely, and spread has typically been due to contaminated food (especially fresh produce) and water. The incubation period is 1–11 days. Infections can be asymptomatic. Cyclosporiasis causes an illness similar to that described for the other pathogens described in this section, with watery diarrhea, abdominal cramps, nausea, fatigue, and anorexia. Fever is seen in 25% of cases. Symptoms typically continue for 2 weeks or longer and may persist for months. Relapses of diarrhea are common. Diarrhea may be preceded by a flu-like prodrome and followed by persistent fatigue. In immunocompromised patients, cyclosporiasis is typically more severe and prolonged, with chronic fulminating watery diarrhea and weight loss.

4. **Sarcocystosis**—Sarcocystis infection may be common in some developing countries, but it is usually asymptomatic. Infection appears to more commonly follow the ingestion of undercooked beef or pork, leading to the development of cysts in muscle, with myalgias, fever, bronchospasm, pruritic rash, lymphadenopathy, and subcutaneous nodules. Ingestion of fecal sporocysts may lead to gastrointestinal symptoms.

5. **Microsporidiosis**—Microsporidia are obligate intracellular protozoans that cause a wide spectrum of diseases. Many infections are of zoonotic origin, but human-to-human transmission has been documented. Infection is mainly by ingestion of spores, but also by direct inoculation of the eyes. In immunocompetent hosts, microsporidian infections most commonly present as self-limited diarrhea. Ocular infections have also been described. Disease from microsporida is seen mainly in immunocompromised persons, particularly those with AIDS. Infections in AIDS patients are most commonly with *E. bieneusi* and *E. intestinalis*. They cause chronic diarrhea, with anorexia, bloating, weight loss, and wasting, especially in those with advanced immunodeficiency. Fever is usually not seen. Other illnesses in immunocompromised persons associated with microsporidians (including the genera *Enteroctozyoon*, *Encephalitozoon*, *Brachiola*, *Vittaforma*, *Pleistophora*, *Trachipleistophora*, and *Microsporidium*) include biliary tract disease (AIDS cholangiopathy), genitourinary infection with cystitis, kidney disease, hepatitis, peritonitis, myositis, respiratory infections including sinusitis, central nervous system infections including granulomatous encephalitis, and disseminated infections. Ocular infections with *Encephalitozoon* species cause conjunctivitis and keratitis, presenting as redness, photophobia, and loss of visual acuity.

**B. Laboratory Findings**

1. **Cryptosporidiosis**—Typically, stool is without blood or leukocytes. Diagnosis is traditionally made by detecting the organism in stool using a modified acid-fast stain; this technique is relatively insensitive, and multiple specimens should be evaluated before ruling out the diagnosis. Of note, routine evaluation for ova and parasites typically does not include a modified acid-fast stain, so this must be specifically requested in many laboratories. Antigen detection offers improved sensitivity and specificity, both of which are well over 90% with a number of available assays,
and these methods may now be considered the optimal means of diagnosis.

2. **Isosporiasis**—Diagnosis of isosporiasis is by examination of stool wet mounts or after modified acid-fast staining, in which the organism is clearly distinguishable from other parasites. Other stains also show the organism. Shedding of oocysts may be intermittent, so the sensitivity of stool evaluation is not high, and multiple samples should be examined. The organism may also be identified in duodenal aspirates or small bowel biopsies.

3. **Cyclosporiasis**—Diagnosis is made by examination of stool wet mounts or after modified acid-fast staining. Multiple specimens may need to be examined to make a diagnosis. The organism can also be identified in small bowel aspirates or biopsy specimens.

4. **Sarcocystosis**—Eosinophilia and elevated creatine kinase may be seen. Diagnosis is by identification of the acid-fast organisms in stool or by identification of trophozoites or bradyzoites in tissue biopsies.

5. **Microsporidiosis**—Diagnosis can be made by identification of organisms in specially stained stool, fluid, or tissue specimens, for example with Weber chromotrope-based stain. Electron microscopy is helpful for confirmation of the diagnosis and speciation. PCR and culture techniques are available but not used routinely.

### Treatment

Most acute infections with these pathogens in immuno-compotent persons are self-limited and do not require treatment. Supportive treatment for severe or chronic diarrhea includes fluid and electrolyte replacement and, in some cases, parenteral nutrition.

1. **Cryptosporidiosis**—Treatment of cryptosporidiosis is challenging. No agent is clearly effective. Modest benefits have been seen in some (but not other) studies with paromomycin, a non-absorbed amino glycoside (25–35 mg/kg orally for 14 days has been used), and nitazoxanide (500 mg–1 g orally twice daily for 3 days in nonimmunocompromised and 2–8 weeks in advanced AIDS patients), which is approved in the United States for this indication. It can cause mild gastrointestinal toxicity. Other agents that have been used with mixed success in AIDS patients with cryptosporidiosis include azithromycin, spiramycin, bovine hyperimmune colostrum, and octreotide. Reversing immunodeficiency with effective antiretroviral therapy is of greatest importance.

2. **Isosporiasis**—Isosporiasis is effectively treated in immunocompetent and immunosuppressed persons with trimethoprim-sulfamethoxazole (160 mg/800 mg orally two to four times daily for 10 days, with the higher dosage for patients with AIDS). An alternative therapy is pyrimethamine (75 mg orally in four divided doses) with folinic acid (10–25 mg/d orally). Maintenance therapy with low-dose trimethoprim-sulfamethoxazole (160 mg/800 mg daily or three times per week) or Fansidar (1 tablet weekly) prevents relapse in those with persistent immunosuppression.

3. **Cyclosporiasis**—Cyclosporiasis is also treated with trimethoprim-sulfamethoxazole (dosing as for isosporiasis). With AIDS, long-term maintenance therapy (160 mg/800 mg three times weekly) helps prevent relapse. For patients intolerant of trimethoprim-sulfamethoxazole, ciprofloxacin (500 mg orally twice daily for 7 days) showed efficacy, albeit with less ability to clear the organism than trimethoprim-sulfamethoxazole.

4. **Sarcocystosis**—For sarcocystosis, no specific treatment is established, but sulfadiazine cleared intestinal cysts in one study.

5. **Microsporidiosis**—Treatment of microsporidiosis is complex. Infections with most species, including those causing gastrointestinal and other manifestations, should be treated with albendazole (400 mg orally twice daily for 2–4 weeks), which has activity against a number of species, but relatively poor efficacy (about 50%) against *E. bieneusi*, the most common microsporidial cause of diarrhea in AIDS patients. Fumagillin, which is used to treat honeybees and fish with microsporidian infections, has shown benefit in clinical trials at a dose of 20 mg three times per day for 14 days; treatment was accompanied by reversible thrombocytopenia. As with cryptosporidiosis, the best means of controlling microsporidiosis in AIDS patients is to restore immune function with effective antiretroviral therapy. Ocular microsporidiosis can be treated with fumagillin solution (3 mg/mL); this probably should be given with concurrent systemic therapy with albendazole. Adjunctive management may include corticosteroids to decrease inflammation and keratoplasty.

### Prevention

Water purification is important for control of these infections. Chlorine disinfection is not effective against cryptosporidial oocysts, so other purification measures are needed. Immunocompromised patients should boil or filter drinking water and should consider avoidance of lakes and swimming pools. Routine precautions (hand-washing, gloves, disinfection) should prevent institutional patient-to-patient spread. Optimal means of preventing microsporidial infections are not well understood, but water purification as discussed above and body substance precautions for immunocompromised and hospitalized individuals are likely effective.

GIARDIASIS

ESSENTIALS OF DIAGNOSIS

- Acute diarrhea; may be profuse and watery.
- Chronic diarrhea with greasy, malodorous stools.
- Abdominal cramps, distention, flatulence, and malaise.
- Cysts or trophozoites in stools.

General Considerations

Giardiasis is a protozoal infection of the upper small intestine caused by the flagellate Giardia lamblia (also called Giardia intestinalis and Giardia duodenalis). The parasite occurs worldwide, most abundantly in areas with poor sanitation. In developing countries, young children are very commonly infected. In the United States and Europe, the infection is the most common intestinal protozoal pathogen; the US estimate is of 100,000 to 2.5 million new infections leading to 5000 hospital admissions yearly. Groups at special risk include travelers to Giardia-endemic areas, those who swallow contaminated water during recreation or wilderness travel, men who have sex with men, and persons with impaired immunity. Outbreaks are common in households, children’s day care centers, and residential facilities, and may occur as a result of contamination of water supplies.

The organism occurs in feces as a flagellated trophozoite and as a cyst. Only the cyst form is infectious by the oral route; trophozoites are destroyed by gastric acidity. Humans are a reservoir for the pathogen; dogs, cats, beavers, and other mammals have been implicated but not confirmed as reservoirs. Under suitable moist, cool conditions, cysts can survive in the environment for weeks to months. Cysts are transmitted as a result of fecal contamination of water or food, by person-to-person contact, or by anal-oral sexual contact. The infectious dose is low, requiring as few as ten cysts. After the cysts are ingested, trophozoites emerge in the duodenum and jejunum. Epithelial damage and mucosal invasion are uncommon. Hypogammaglobulinemia, low secretory IgA levels in the gut, achlorhydria, and malnutrition favor the development of infection.

Clinical Findings

A. Symptoms and Signs

It is estimated that about 50% of infected persons have no discernible infection, about 10% become asymptomatic cyst passers, and 25–50% develop an acute diarrheal syndrome. Acute diarrhea may clear spontaneously but is commonly followed by chronic diarrhea. The incubation period is usually 1–3 weeks but may be longer. The illness may begin gradually or suddenly. Cysts may not be detected in the stool at the onset of the illness. The acute phase may last days or weeks, and is usually self-limited, although cyst excretion may be prolonged. The initial illness may include profuse watery diarrhea, and hospitalization may be required due to dehydration, particularly in young children. Typical symptoms of chronic disease are abdominal cramps, bloat, flatulence, nausea, malaise, and anorexia. Fever and vomiting are uncommon. Diarrhea is usually not severe in the chronic stage of infection; stools are greasy or frothy and foul smelling, without blood, pus, or mucus. The diarrhea may be daily or recurrent; intervening periods may include constipation. Symptoms can persist for weeks to months. Weight loss is frequent. Chronic disease can include malabsorption, including fat- and protein-losing enteropathy and vitamin deficiencies.

B. Laboratory Findings

Most patients seek medical attention after having been ill for over a week, commonly with weight loss of 5 kg or more. Stool is generally without blood or leukocytes. Diagnosis is traditionally made by the identification of trophozoites or cysts in stool. A wet mount of liquid stool may identify motile trophozoites. Stained fixed specimens may show cysts or trophozoites. Sensitivity of stool analysis is not ideal, estimated at 50–80% for a single specimen and over 90% for three specimens. Sampling of duodenal contents with a string test or biopsy is no longer generally recommended, but biopsies may be helpful in very ill or immunocompromised patients. When giardiasis is suspected, antigen assays may be simpler and cheaper than repeated stool examinations, but these tests will not identify other stool pathogens. Multiple tests, which identify antigens of trophozoites or cysts, are available. They are generally quite sensitive (85–98%) and specific (90–100%).

Treatment

The treatments of choice for giardiasis are metronidazole (250 mg orally three times daily for 5–7 days) or tinidazole (2 g orally once daily for 5 days) to have equivalent efficacy and fewer side effects compared with metronidazole, and so it may be considered another first-line agent for giardiasis. Nitazoxanide (500 mg orally twice daily for 3 days) is generally well tolerated but may cause mild gastrointestinal side effects. Other drugs with activity against Giardia include furazolidone (100 mg orally four times a day for 7 days), which is about as effective as the other named drugs but causes gastrointestinal side effects, and paromomycin (500 mg orally three times a day for 7 days), which appears to have somewhat lower efficacy but unlike metronidazole, tinidazole, and furazolidone is safe in pregnancy. Symptomatic giardiasis should always be treated.

Treatment of asymptomatic patients should be considered, since they can transmit the infection to others. With a presumptive diagnosis but negative diagnostic studies, an
empiric course of treatment is sometimes appropriate. Household or day care contacts with an index case should be tested and treated if infected.

► Prevention

Community chlorination (0.4 mg/L) of water is relatively ineffective for inactivating cysts, so filtration is required. For wilderness or international travelers, bringing water to a boil for 1 minute or filtration with a pore size < 1 mcu are adequate. In day care centers, appropriate disposal of diapers and frequent hand washing are essential.

OTHER INTESTINAL FLAGELLATE INFECTIONS

Balantidium coli is a large ciliated intestinal protozoan found worldwide, but particularly in the tropics. Pigs are the main reservoir. The infection is rare in humans, and results from ingestion of cysts passed in stools of humans or swine. In the new host, the cyst wall dissolves and the trophozoite may invade intestinal mucosa, causing abscesses and ulcerations. Many infections are asymptomatic. Chronic infections may cause recurrent diarrhea or dysentery. Deaths have occurred from intestinal perforation and hemorrhage.

Dientamoeba fragilis is a protozoan that commonly causes infection without symptoms, so its role in human disease remains somewhat controversial. Symptoms attributed to the pathogen include diarrhea, abdominal pain, and anorexia. Other flagellates may infect humans, are generally considered nonpathogens, but may be markers for fecal-oral contamination.

Diagnosis of balantidiasis is established by finding trophozoites or cysts in stool, or in ulcer scrapings of the large bowel. D fragilis infection can be hard to diagnose because it only exists in the trophozoite form; the sensitivity of evaluation of three stools is 70–90%. The treatment of choice for balantidiasis is tetracycline, 500 mg orally four times daily for 10 days. The alternative is iodoquinol (diiodohydroxyquin), 650 mg orally three times daily for 21 days, and metronidazole, paromomycin, and nitazoxanide have also been used successfully. D fragilis infections have been successfully treated with metronidazole, iodoquinol, paromomycin, and tetracycline, but failures have been reported recently with metronidazole; all the regimens are the same as for balantidiasis.

TRICHOMONIASIS

► General Considerations

Trichomoniasis is caused by the protozoan Trichomonas vaginalis and is among the most common sexually transmitted diseases, causing vaginitis in women and nongonococcal urethritis in men. It can also occasionally be acquired by other means, since it can survive in moist environments for several hours.

► Clinical Findings

A. Symptoms and Signs

_T vaginalis_ is often harbored asymptptomatically. For women with symptomatic disease, after an incubation period of 5 days to 4 weeks, a vaginal discharge develops, often with vulvovaginal discomfort, pruritus, dysuria, dyspareunia, or abdominal pain. Examination shows a copious discharge, which is usually not foul smelling but is often frothy and yellow or green in color. Inflammation of the vaginal walls and cervix with punctate hemorrhages are common. Most men infected with _T vaginalis_ are asymptomatic, but it can be isolated from about 10% of men with nongonococcal urethritis. In men with trichomonal urethritis, the urethral discharge is generally more scanty than with other causes of urethritis.

B. Diagnostic Testing

Diagnosis is typically made by identifying the organism in vaginal or urethral secretions. Examination of wet mounts will show motile organisms. Tests for bacterial vaginoses (pH > 4.5, fishy odor after addition of potassium hydroxide) are often positive with trichomoniasis. Rapid antigen and nucleic acid amplification tests that are highly specific and much more sensitive than wet mounts are available but are not yet widely used.

► Treatment

The treatment of choice is metronidazole or tinidazole, each as a 2 g single oral dose. Tinidazole may be better tolerated and active against some resistant parasites. Toxicities of these drugs are discussed in the section on amebiasis. If the large single dose cannot be tolerated, an alternative metronidazole dosage is 500 mg orally twice daily for 1 week. All infected persons should be treated, even if asymptomatic, to prevent subsequent symptomatic disease and limit spread. Treatment failure suggests reinfection, but metronidazole-resistant organisms have been reported. These may be treated with tinidazole, longer courses of metronidazole, furazolidone, or other experimental therapies (see Chapter 18).
Schistosomiasis, which affects more than 200 million persons worldwide, leads to severe consequences in 20 million persons and about 100,000 deaths annually. The disease is caused by five species of trematode blood flukes. Four species cause intestinal schistosomiasis, with infection of mesenteric venules: *Schistosoma mansoni*, which is present in Africa, the Arabian peninsula, South America, and the Caribbean; *Schistosoma japonicum*, which is endemic in China and Southeast Asia; *Schistosoma mekongi*, which is endemic near the Mekong River in Southeast Asia; and *Schistosoma intercalatum*, which occurs in parts of Africa. *Schistosoma haematobium* causes urinary schistosomiasis, with infection of venules of the urinary tract, and is endemic in Africa and the Middle East. Transmission of schistosomiasis is focal, with greatest prevalence in poor rural areas. Control efforts have diminished transmission significantly in many areas, but high level transmission remains common in sub-Saharan Africa and some other areas. Prevalence of infection and illness typically peaks at about 15–20 years of age.

Humans are infected with schistosomes after contact with fresh water containing cercariae released by infected snails. Infection is initiated by penetration of skin or mucous membranes. After penetration, schistosomulae migrate to the portal circulation, where they rapidly mature. After about 6 weeks, adult worms mate, and migrate to terminal mesenteric or bladder venules, where females deposit their eggs. Some eggs reach the lumen of the bowel or bladder and are passed with feces or urine, while others are retained in the bowel or bladder wall or transported in the circulation to other tissues, in particular the liver. Disease in endemic areas is primarily due to a host response to eggs, with granuloma formation and inflammation, eventually leading to fibrosis. Chronic infection can result in scarring of mesenteric or vesicular blood vessels, leading to portal hypertension and alterations in the urinary tract. In previously uninfected individuals, such as travelers with fresh water contact in endemic regions, acute schistosomiasis may occur, with a febrile illness 2–8 weeks after infection.

### Clinical Findings

#### A. Symptoms and Signs

1. **Cercarial dermatitis**—Following cercarial penetration, localized erythema develops in some individuals, which can progress to a pruritic maculopapular rash that persists for some days. Dermatitis can be caused by human schistosomes and, in non-tropical areas, by bird schistosomes that cannot complete their life cycle in humans (swimmer’s itch).

2. **Acute schistosomiasis (Katayama syndrome)**—A febrile illness may develop 2–8 weeks after exposure in persons without prior infection, most commonly after heavy infection with *S mansoni* or *S japonicum*. Presenting symptoms and signs include acute onset of fever; headache; myalgias; cough; malaise; urticaria; diarrhea, which may be bloody; hepatosplenomegaly; lymphadenopathy; and pulmonary infiltrates. Localized lesions may occasionally cause severe manifestations, including CNS abnormalities and death. Acute schistosomiasis usually resolves in 2–8 weeks.

3. **Chronic schistosomiasis**—Many infected persons have light infections and are asymptomatic, but an estimated 50–60% have symptoms and 3–10% have advanced organ damage. Asymptomatic infected children may suffer from anemia and growth retardation. Symptomatic patients with intestinal schistosomiasis typically experience abdominal pain, fatigue, diarrhea, and hepatomegaly. Over years, anorexia, weight loss, weakness, colonic polyps, and features of portal hypertension develop. Late manifestations include hematemesis from esophageal varices, hepatic failure, and pulmonary hypertension. Urinary schistosomiasis may present within months of infection with hematuria and dysuria, most commonly in children and young adults. Fibrotic changes in the urinary tract can lead to hydroureret, hydronephrosis, bacterial urinary infections and, ultimately, kidney disease or bladder cancer.

#### B. Laboratory Findings

Microscopic examination of stool or urine for eggs, evaluation of tissue, or serologic tests establish the diagnosis. Characteristic eggs can be identified on smears of stool or urine, but filtration or concentration techniques can improve yields. Quantitative tests that yield > 400 eggs per
gram of feces or 10 mL of urine are indicative of heavy infections with increased risk of complications. Diagnosis can also be made by biopsy of the rectum, colon, liver, or bladder. Serologic tests include an ELISA available from the CDC that is 99% specific for all species. The test is 99% sensitive for S mansoni, 95% sensitive for S haematobium, but < 50% sensitive for S japonicum. Species-specific immunoblots can increase sensitivity. In acute schistosomiasis, leukocytosis and marked eosinophilia may occur; serologic tests may become positive before eggs are seen in stool or urine. After therapy, eggs may be shed in stool or urine for months, and so the identification of eggs in fluids or tissue or positive serologic tests cannot distinguish past or active disease. Tests for egg viability are available. With a diagnosis of schistosomiasis, evaluation for the extent of disease is warranted, including liver function studies and imaging of the liver with intestinal disease and ultrasound or other imaging studies of the urinary system in urinary disease.

## Treatment

Treatment is indicated for all schistosome infections. In areas where recurrent infection is common, treatment is valuable in reducing worm burdens and limiting clinical complications. The drug of choice for schistosomiasis is praziquantel. The drug is administered for 1 day at an oral dose of 40 mg/kg (in one or two doses) for S mansoni, S haematobium, and S intercalatum infections and a dose of 60 mg/kg (in two or three doses) for S japonicum and S mekongi. Cure rates are generally > 80% after a single treatment, and those not cured have marked reduction in the intensity of infection. Praziquantel is active against invading cercariae but not developing schistosomulae. Therefore, the drug may not prevent illness when given after exposure and, for recent infections, a repeat course after a few weeks may be appropriate. Praziquantel may be used during pregnancy. Resistance to praziquantel has been reported. Toxicities include abdominal pain, diarrhea, urticaria, headache, nausea, vomiting, and fever, and may be due both to direct effects of the drug and response to dying worms. Alternative therapies are oxamniquine for S mansoni infection and metrifonate for S haematobium infection. Both of these drugs currently have limited availability (they are not available in the United States), and resistance may be a problem. No second-line drug is available for S japonicum infections. The antimalarial drug artemether has activity against schistosomulae and adult worms and may be effective in chemoprophylaxis; however, it is expensive, and long-term use in malarious areas might select for resistant malaria parasites. With severe disease, use of corticosteroids in conjunction with praziquantel may decrease complications. Treatment should be followed by repeat examinations for eggs about every 3 months for 1 year after therapy, with re-treatment if eggs are seen.

## Prevention

Travelers to endemic areas should avoid fresh water exposure. Vigorous toweling after exposure may limit cercarial penetration. Chemoprophylaxis with artemether has shown efficacy but is not standard practice. Community control of schistosomiasis includes improved sanitation and water supplies, elimination of snail habitats, and intermittent administration of treatment to limit worm burdens.

---

**LIVER, LUNG, AND INTESTINAL FLUKES**

### FASCIOLIASIS

Infection by *Fasciola hepatica*, the sheep liver fluke, results from ingestion of encysted metacercariae on watercress or other aquatic vegetables. Infection is prevalent in sheep-raising areas in many countries, especially parts of South America, the Middle East, and southern Europe. *Fasciola gigantica* has a more restricted distribution in Asia and Africa and causes similar findings. Eggs are passed from host feces into fresh water, leading to infection of snails, and then deposition of metacercariae on vegetation. In humans, metacercariae excyst, penetrate into the peritoneum, migrate through the liver, and mature in the bile ducts, where they cause local necrosis and abscess formation.

Two clinical syndromes are seen, related to acute migration of worms and chronic infection of the biliary tract. Symptoms related to migration of larvae present 6–12 weeks after ingestion. Typical findings are abdominal pain, fever, malaise, weight loss, urticaria, eosinophilia, and leukocytosis. Tender hepatomegaly and elevated liver function tests may be seen. Rarely, migration to other organs may lead to localized disease. The symptoms of worm migration subside after 2–4 months, followed by asymptomatic infection by adult worms or intermittent symptoms of biliary obstruction, with biliary colic and, at times, findings of cholangitis. Early diagnosis is difficult, as eggs are not found in the feces during the acute migratory phase of infection. Clinical suspicion should be based on clinical findings and marked eosinophilia in at risk individuals. CT and other imaging studies show hypodense migratory lesions of the liver. Serologic assays may be positive about 1 month before eggs are seen in stool, but specificities of available tests are not ideal. Definitive diagnosis is made by the identification of characteristic eggs in stool. Repeated examinations may be necessary. In chronic infection, imaging studies show masses obstructing the extrahepatic biliary tract.

Fascioliasis is unusual among fluke infections, in that it does not respond well to treatment with praziquantel. The
treatment of choice is triclabendazole, which is also used in veterinary medicine, but is not available in the United States. Standard dosing of 10 mg/kg orally in a single dose or two doses over 12 hours achieves a cure rate of about 80%, but repeat dosing is indicated if abnormal radiologic findings or eosinophilia do not resolve. The second-line drug for fascioliasis is bithionol (30–50 mg/kg/d orally in three divided doses on alternate days for 10–15 days); this drug is no longer available in the United States. Treatment with either drug can be accompanied by abdominal pain and other gastrointestinal symptoms. Prevention of fascioliasis involves avoidance of ingestion of raw aquatic plants.

**CLONORCHIASIS & OPISTHORCHIASIS**

Infection by *Clonorchis sinensis*, the Chinese liver fluke, is endemic in areas of Japan, Korea, China, Taiwan, Southeast Asia, and the far eastern part of Russia. Millions of people are affected and, in some communities, prevalence can reach over 80%. Opisthorchiasis is principally caused by *Opisthorchis felineus* (regions of the former Soviet Union) or *Opisthorchis viverrini* (Thailand, Laos, Vietnam). Clonorchiasis and opisthorchiasis are clinically indistinguishable. Parasite eggs are shed into water in human or animal feces, where they infect snails, which release cercariae, which infect fish. Human infection follows ingestion of raw, undercooked, or pickled freshwater fish containing metacercariae. These parasites encyst in the duodenum and ascend into the biliary tract, where they mature and remain for many years, shedding eggs in the bile.

Most patients harbor few parasites and are asymptomatic. An acute illness can occur 2–3 weeks after initial infection, with fever, abdominal pain, tender hepatomegaly, urticaria, and eosinophilia. The acute syndrome is difficult to diagnose, since ova may not appear in the feces until 3–4 weeks after onset of symptoms. In chronic heavy infections, findings include abdominal pain, anorexia, weight loss, and tender hepatomegaly. More serious findings can include recurrent bacterial cholangitis and sepsis, cholecystitis, liver abscesses, and pancreatitis. An increased risk of cholangiocarcinoma has been documented.

Early diagnosis is presumptive, based on clinical findings and epidemiology. Subsequent diagnosis is made by finding characteristic eggs in stool or duodenal or biliary contents. Repeated concentration tests of stool may be necessary. Imaging studies show characteristic biliary tract dilatations with filling defects due to flukes. Serologic tests can be helpful but are limited by suboptimal specificity.

The drug of choice is praziquantel, 25 mg/kg orally three times daily for 2 days, which provides cure rates over 95%. One day of treatment may be sufficient. Re-treatment may be required, especially in some areas with known decreased praziquantel efficacy. The second-line drug is albendazole (400 mg orally twice daily for 7 days), which appears to be somewhat less effective.

**PARAGONIMIASIS**

Eight species of *Paragonimus* lung flukes cause human disease. The most important is *Paragonimus westermani*.

*Paragonimus* species are endemic in East Asia, Oceania, West Africa, and South America, where millions of persons are infected. Eggs are released into fresh water, where parasites infect snails, and then cercariae infect crabs and crayfish. Human infection follows consumption of raw, undercooked, or pickled freshwater shellfish. Metacercariae then encyst, penetrate into the peritenum, and pass into the lungs, where they mature into adult worms over about 2 months.

Most persons have moderate worm burdens and are asymptomatic. In symptomatic cases, abdominal pain and diarrhea develop 2 days to 2 weeks after infection, followed by fever, cough, chest pain, urticaria, and eosinophilia. Acute symptoms may last for several weeks. Chronic infection can cause cough productive of brown sputum, hemoptysis, dyspnea, and chest pain, with progression to chronic bronchitis, bronchiectasis, bronchopneumonia, lung abscess, and pleural disease. Ectopic infections can cause disease in other organs, most commonly the CNS, where disease can present with seizures, headaches, and focal neurologic findings due to parasite meningitis and to intracerebral lesions.

The diagnosis of paragonimiasis is made by identifying characteristic eggs in sputum or stool or identifying worms in biopsied tissue. Multiple examinations and concentration techniques may be needed. Serologic tests may be helpful; an ELISA available from the CDC has sensitivity and specificity > 95%. Chest radiographs may show varied abnormalities of the lungs or pleura, including infiltrates, nodules, cavities, and fibrosis, and the findings can be confused with those of tuberculosis. With CNS disease, skull radiographs can show clusters of calcified cysts, and CT or MRI can show clusters of ring-enhancing lesions.

Treatment is with praziquantel (25 mg/kg orally three times daily for 2 days), which provides efficacy of at least 90%. Alternative therapies are bithionol and triclabendazole. As with cysticercosis, for cerebral paragonimiasis, praziquantel should generally be used with corticosteroids. Chronic infection may lead to permanent lung dysfunction and pleural disease requiring drainage procedures.

**INTESTINAL FLUKES**

The large intestinal fluke, *Fasciolaopsis buski*, is a common parasite of pigs and humans in eastern and southern Asia. Eggs shed in stools hatch in fresh water, followed by infection of snails, and release of cercariae that encyst on aquatic plants. Humans are infected by eating uncooked plants, including water chestnuts, bamboo shoots, and watercress. Adult flukes mature in about 3 months and live in the small intestine attached to the mucosa, leading to local inflammation and ulceration. Other intestinal flukes that cause similar syndromes include *Heterophyes* (North Africa and Turkey) and *Metagonimus* (East Asia) species; these species are transmitted by undercooked freshwater fish.

Infections with intestinal flukes are often asymptomatic, although eosinophilia may be marked. In symptomatic cases, after an incubation period of 1–2 months,
manifestations include epigastric pain and diarrhea. Other gastrointestinal symptoms, ileus, edema, and ascites may be seen uncommonly. Diagnosis is based on identification of characteristic eggs or adult flukes in the stool. In contrast to other fluke infections, illness more than 6 months after travel in an endemic area is unlikely. The drug of choice is praziquantel, 25 mg/kg orally as a single dose. Alternative therapies are triclabendazole and niclosamide (for most species).

CHAPTER 35

CESTODE INFECTIONS

NONINVASIVE CESTODE INFECTIONS

The four major tapeworms that cause noninvasive infections in humans are the beef tapeworm *Taenia saginata*, the pork tapeworm *Taenia solium*, the fish tapeworm *Diphyllobothrium latum*, each of which can reach many meters in length, and the dwarf tapeworm *Hymenolepis nana*. *Taenia* and *Hymenolepis* species are broadly distributed, especially in the tropics; *D latum* is most prevalent in temperate regions. Other tapeworms that can cause noninvasive human disease include the rodent tapeworm *Hymenolepis diminuta*, the dog tapeworm *Dipylidium caninum*, and other *Taenia* and *Diphyllobothrium* species. Invasive tapeworm infections, including *T solium* (when infective eggs, rather than cysticerci are ingested) and *Echinococcus* species, will be discussed separately.

1. Beef Tapeworm

Infection is most common in cattle breeding areas. Humans are the definitive host. Gravid segments of *T saginata* are passed in human feces to soil, where they are ingested by grazing animals, especially cattle. The eggs then hatch to release embryos that encyst in muscle as cysticerci. Humans are infected by eating raw or undercooked infected beef. Most individuals infected with *T saginata* are asymptomatic, but abdominal pain and other gastrointestinal symptoms may be present. Eosinophilia is common. The most common presenting finding is the passage of proglottids in the stool.

2. Pork Tapeworm

*T solium* is transmitted to pigs that ingest human feces. Humans can be either the definitive host (after consuming undercooked pork, leading to tapeworm infection) or the intermediate host (after consuming food contaminated with human feces containing *T solium* eggs, leading to cysticercosis, which is discussed under invasive tapeworm infections). As with the beef tapeworm, infection with *T solium* adult worms is generally asymptomatic, but gastrointestinal symptoms may occur. Infection is generally recognized after passage of proglottids. Autoinfection with eggs can progress to cysticercosis.

3. Fish Tapeworm

Infection with *D latum* follows ingestion of undercooked freshwater fish, most commonly in temperate regions. Eggs from human feces are taken up by crustaceans, these are eaten by fish, which are then infectious to humans. Infection with multiple worms over many years can occur. Infections are most commonly asymptomatic, but nonspecific gastrointestinal symptoms, including diarrhea, may occur. Diagnosis usually follows passage of proglottids. Prolonged heavy infection can lead to megaloblastic anemia and neuropathy from vitamin B12 deficiency, which is due to infection-induced dissociation of the vitamin from intrinsic factor and to utilization of the vitamin by worms.

4. Dwarf Tapeworm

*H nana* is the only tapeworm that can be transmitted between humans. Infections are common in warm areas, especially with poor hygiene and institutionalized populations. Infection follows ingestion of food contaminated with human feces. Eggs hatch in the intestines, where oncospheres penetrate the mucosa, encyst as cysticercoid larvae, and then rupture after about 4 days to release adult worms. Autoinfection can lead to amplification of infection. Infection with *H nana*, the related rodent tapeworm *H diminuta*, or the dog tapeworm *D caninum* can also follow accidental ingestion of infected insects. *H nana* are dwarf in size relative to other tapeworms but can reach 5 cm in length. Heavy infection is common, especially in children, and can be accompanied by abdominal discomfort, anorexia, and diarrhea.

Laboratory Findings

Diagnosis is usually made based on the identification of characteristic eggs or proglottids in stool. Egg release may be irregular, so examination of multiple specimens or concentration techniques may be needed.

Treatment

The treatment of choice for noninvasive tapeworm infections is praziquantel. A single dose of praziquantel (5–10 mg/kg orally) is highly effective, except for *H nana*, for which the dosage is 25 mg/kg. Treatment of *H nana* is more difficult, as the drug is not effective against maturing cysts. Therefore, with heavy infections with this parasite a repeat treatment after 1 week, and screening after therapy to document cure are appropriate. Therapy can be accompanied by headache, malaise, dizziness, abdominal pain, and nausea.

The alternative therapy for these infections is niclosamide. A single dose of niclosamide (2 g chewed) is effective against *D latum*, *Taenia*, and *D caninum* infections. For *H nana*, therapy is continued daily for 1 week. Niclosamide may cause nausea, malaise, and abdominal pain.
Cysticercosis is due to tissue infection with cysts of *T. solium* that develop after humans ingest food contaminated with eggs from human feces, thus acting as an intermediate host for the parasite. Prevalence is high where the parasite is endemic, in particular Mexico, Central and South America, the Philippines, and Southeast Asia. An estimated 20 million persons are infected with cysticerci yearly, leading to about 400,000 persons with neurologic symptoms and 50,000 deaths. Antibody prevalence rates up to 10% are recognized in some endemic areas, and the infection is one of the most important causes of seizures in the developing world and in immigrants to the United States from endemic countries.

### Clinical Findings

#### A. Symptoms and Signs

Neurocysticercosis can cause intracerebral, subarachnoid, and spinal cord lesions and intraventricular cysts. Single or multiple lesions may be present. Lesions may persist for years before symptoms develop, generally due to local inflammation or ventricular obstruction. Presenting symptoms include seizures, focal neurologic deficits, altered cognition, and psychiatric disease. Symptoms develop more quickly with intraventricular cysts, with findings of hydrocephalus and meningeal irritation, including severe headache, vomiting, papilledema, and visual loss. A particularly aggressive form of the disease, racemose cysticercosis, involves proliferation of cysts at the base of the brain, leading to alterations of consciousness and death. Spinal cord lesions can present with progressive focal findings.

Cysticercosis of other organ systems is usually clinically benign. Involvement of muscles can uncommonly cause discomfort and is identified by radiographs of muscle showing multiple calcified lesions. Subcutaneous involvement presents with multiple painless palpable skin lesions. Involvement of the eyes can present with ptosis due to extraocular muscle involvement or intraocular abnormalities.

#### B. Laboratory Findings

CSF examination may show lymphocytic or eosinophilic pleocytosis, decreased glucose, and elevated protein. Serology plays an important role in diagnosis. ELISAs with sensitivity and specificity over 90% are available.

#### C. Imaging

The diagnosis of neurocysticercosis can be difficult. With neuroimaging by CT or MRI, multiple parenchymal cysts are most typically seen. Parenchymal calcification is also common. Ventricular cysts may be difficult to visualize, with MRI offering better sensitivity than CT.

#### Treatment

The medical management of neurocysticercosis is controversial, as the benefits of cyst clearance must be weighed against potential harm of an inflammatory response to dying worms. Antihelminthic therapy hastens radiologic improvement in parenchymal cysticercosis. However, some randomized trials have shown that corticosteroids alone are as effective as specific therapy plus corticosteroids for controlling seizures, and some reports have shown exacerbation of disease after antihelminthic therapy. Active lesions with a high likelihood of progression, such as intraventricular cysts, may benefit from therapy. At the other end of the spectrum, inactive calcified lesions probably do not benefit from therapy. Overall, it remains difficult to determine when treatment is indicated. When treatment is deemed appropriate, standard therapy consists of albendazole (10–15 mg/kg/d orally for 8 days) or praziquantel (50 mg/kg/d orally for 15–30 days). Albendazole is preferably preferred, since it has shown better efficacy in some comparisons and since corticosteroids appear to lower circulating praziquantel levels but increase albendazole levels. Increasing the dosage of albendazole to 30 mg/kg/d orally may improve outcomes. Corticosteroids are usually administered concurrently, but dosing is not standardized. Patients should be observed for evidence of localized inflammatory responses. Anticonvulsant therapy is provided if needed, and shunting is performed if required for elevated intracranial pressure. Surgical removal of cysts may be helpful for some difficult cases of neurocysticercosis and for symptomatic non-neurologic disease.

2. Echinococcosis

ESSENTIALS OF DIAGNOSIS
- History of exposure to dogs or wild canines in an endemic area.
- Large cystic lesions, most commonly of the liver or lung.
- Positive serologic tests.

General Considerations
Echinococcosis occurs when humans are intermediate hosts for canine tapeworms. Infection is acquired by ingesting food contaminated with canine feces containing parasite eggs. The principal species that infect humans are *Echinococcus granulosus*, which causes cystic hydatid disease, and *Echinococcus multilocularis*, which causes alveolar hydatid disease. *E. granulosus* is transmitted by domestic dogs in areas with livestock (sheep, goats, camels, and horses) as intermediate hosts, including Africa, the Middle East, southern Europe, South America, Central Asia, Australia, New Zealand, and the southwestern United States. *E. multilocularis*, which much less commonly causes human disease, is transmitted by wild canines, and endemic in northern forest areas of the northern hemisphere, including central Europe, Siberia, northern Japan, northwestern Canada, and western Alaska. An increase in the fox population in Europe has been associated with an increase in human cases. The disease range has also extended southward in Central Asia and China. Other species that cause limited disease in humans are endemic in South America and China.

After humans ingest parasite eggs, the eggs hatch in the intestines to form oncospheres, which penetrate the mucosa, enter the circulation, and encyst in specific organs as hydatid cysts. *E. granulosus* forms cysts most commonly in the liver (65%) and lungs (25%), but the cysts may develop in any organ, including the brain, bones, skeletal muscles, kidneys, and spleen. Cysts are most commonly single. The cysts can persist and slowly grow for many years.

Clinical Findings
A. Symptoms and Signs
Infections are commonly asymptomatic and may be noted incidentally on imaging studies or present with symptoms caused by an enlarging or superinfected mass. Findings may include abdominal or chest pain, biliary obstruction, cholangitis, portal hypertension, cirrhosis, bronchial obstruction leading to segmental lung collapse, and abscesses. Cyst leakage or rupture may be accompanied by a severe allergic reaction, including fever and hypotension. Seeding of cysts after rupture may extend the infection to new areas.

*E. multilocularis* generally causes a more aggressive disease than *E. granulosus*, with initial infection of the liver, but then local and distant spread commonly suggesting a malignancy. Symptoms based on the areas of involvement gradually worsen over years, with the development of obstructive findings in the liver and elsewhere.

B. Laboratory Findings
Serologic tests, including ELISA and immunoblot, offer sensitivity and specificity over 80% for *E. granulosus* liver infections, but lower sensitivity for involvement of other organs. Serologic tests may also distinguish the two major echinococcal infections.

C. Imaging
Diagnosis is usually based on imaging studies, including ultrasonography, CT, and MRI. In *E. granulosus* infection, a large cyst containing daughter cysts is highly suggestive of the diagnosis. In *E. multilocularis* infection, imaging shows an irregular mass, often with areas of calcification.

Treatment
Treatment of cystic hydatid disease has traditionally involved cautious surgical resection of cysts, with care not to rupture cysts during removal. Injection of a cysticidal agent was used to limit spread in the case of rupture. Newer management algorithms include treatment with albendazole, often in conjunction with surgery. When used alone, as in cases where surgery is not possible, albendazole (10–15 mg/kg/d orally) has demonstrated efficacy; with courses of 3 months or longer duration, in some cases with alternating cycles of treatment and rest. Mebendazole (40–50 mg/kg/d orally) is an alternative drug, and praziquantel may also be effective. In some cases, medical therapy is begun, with surgery performed if disease persists after some months of therapy. Another approach, in particular with inoperable cysts, is percutaneous aspiration, injection, and reaspiration (PAIR). In this approach (which should not be used if cysts communicate with the biliary tract), patients receive anthelminthic therapy, and the cyst is partially aspirated. After diagnostic confirmation by examination for parasite protoscolices, a sclerosing agent (such as 95% ethanol, hypertonic saline, or 0.5% cetrimide) is injected. PAIR includes a small risk of anaphylaxis, which has been reported in about 2% of procedures, but death due to anaphylaxis has been rare. Treatment of alveolar cyst disease is challenging, generally relying on wide surgical resection of lesions. Therapy with albendazole before or during surgery may be beneficial and may also provide improvement or even cure in inoperable cases.

3. Other Invasive Cestode Infections
Ingestion of aquatic copepods infected with larvae of *Spirometra* canine or feline tapeworms can lead to sparganosis, especially in South America and East Asia. Infection can also come from ingestion of undercooked infected meat (including mammals, birds, reptiles, and amphibians) or from use of frog or snake-meat poultices. The worms penetrate the intestinal wall or skin and migrate to various tissues. Inflammatory lesions, most commonly of the skin
or else, eyes, are typically present. In cerebral sparganosis, an intense inflammatory response to worms can lead to severe neurologic disease. Diagnosis is by biopsy or visualization of the parasite. Treatment consists of surgical resection or local injection of ethanol. Antihelminthics do not appear to be helpful. Other non-human tapeworms can also cause localized and CNS inflammatory lesions. These are also managed with surgical resection.

**Clinical Findings**

Most persons with *Ascaris* infection are asymptomatic. In a small proportion of patients, symptoms develop during migration of worms through the lungs, with fever, nonproductive cough, chest pain, dyspnea, and eosinophilia, occasionally with eosinophilic pneumonia. Rarely, larvae lodge ectopically in the brain, kidney, eye, spinal cord, and other sites and may cause local symptoms.

Light intestinal infections usually produce no symptoms. With heavy infection, abdominal discomfort may be seen. Adult worms may also migrate and be coughed up, be vomited, or may emerge through the nose or anus. They may also migrate into the common bile duct, pancreatic duct, appendix, and other sites, which may lead to cholangitis, cholecystitis, pyogenic liver abscess, pancreatitis, obstructive jaundice, or appendicitis. With very heavy infestations, masses of worms may cause intestinal obstruction, volvulus, intussusception, or death. Although severe manifestations of infection are uncommon, the very high prevalence of ascariasis leads to large numbers of individuals, especially children, with important sequelae. Moderate to high worm loads in children are also associated with nutritional abnormalities due to decreased appetite and food intake, and also decreased absorption of nutrients.

The diagnosis of ascariasis is made after adult worms emerge from the mouth, nose, or anus, or by identifying characteristic eggs in the feces. Due to the very high egg burden, concentration techniques are generally not needed. Imaging studies demonstrate worms, with filling defects in contrast studies and at times evidence of intestinal or biliary obstruction. Eosinophilia is marked during worm migration but may be absent during intestinal infection.

**Treatment**

All infections should ideally be treated. Treatments of choice are albendazole (single 400 mg oral dose), mebendazole (single 500 mg oral dose or 100 mg twice daily for 3 days), or pyrantel pamoate (single 11 mg/kg oral dose, maximum 1 g). These drugs are all well tolerated but may cause mild gastrointestinal toxicity. They are considered safe for children above 1 year of age and in pregnancy, although use in the first trimester is best avoided. Intestinal obstruction usually responds to conservative management and antihelminthic therapy. Surgery may be required for appendicitis and other gastrointestinal complications.

**Intestinal Nematode (Roundworm) Infections**

**Ascariasis**

- **Essentials of Diagnosis**
  - Transient cough, urticaria, pulmonary infiltrates, eosinophilia.
  - Nonspecific abdominal symptoms.
  - Eggs in stool; adult worms occasionally passed.

- **General Considerations**

  *Ascaris lumbricoides* is the most common of the intestinal helminths, infecting about a quarter of the world’s population, with estimates of over a billion infections, 12 million acute cases, and 10,000 or more deaths annually. Prevalence is high wherever there is poor hygiene and sanitation or where human feces are used as fertilizer. Heavy infections are most common in children.

  Infection follows ingestion of eggs in contaminated food. Larvae hatch in the small intestine, penetrate into the bloodstream, migrate to the lungs, and then travel via airways back to the gastrointestinal tract, where they develop to adult worms, which can be up to 40 cm in length, and live for 1–2 years.

  Most infected persons are asymptomatic. In a small proportion of patients, symptoms develop during migration of worms through the lungs, with fever, nonproductive cough, chest pain, dyspnea, and eosinophilia, occasionally with eosinophilic pneumonia. Rarely, larvae lodge ectopically in the brain, kidney, eye, spinal cord, and other sites and may cause local symptoms.

  Light intestinal infections usually produce no symptoms. With heavy infection, abdominal discomfort may be seen. Adult worms may also migrate and be coughed up, be vomited, or may emerge through the nose or anus. They may also migrate into the common bile duct, pancreatic duct, appendix, and other sites, which may lead to cholangitis, cholecystitis, pyogenic liver abscess, pancreatitis, obstructive jaundice, or appendicitis. With very heavy infestations, masses of worms may cause intestinal obstruction, volvulus, intussusception, or death. Although severe manifestations of infection are uncommon, the very high prevalence of ascariasis leads to large numbers of individuals, especially children, with important sequelae. Moderate to high worm loads in children are also associated with nutritional abnormalities due to decreased appetite and food intake, and also decreased absorption of nutrients.

  The diagnosis of ascariasis is made after adult worms emerge from the mouth, nose, or anus, or by identifying characteristic eggs in the feces. Due to the very high egg burden, concentration techniques are generally not needed. Imaging studies demonstrate worms, with filling defects in contrast studies and at times evidence of intestinal or biliary obstruction. Eosinophilia is marked during worm migration but may be absent during intestinal infection.

  **Treatment**

  All infections should ideally be treated. Treatments of choice are albendazole (single 400 mg oral dose), mebendazole (single 500 mg oral dose or 100 mg twice daily for 3 days), or pyrantel pamoate (single 11 mg/kg oral dose, maximum 1 g). These drugs are all well tolerated but may cause mild gastrointestinal toxicity. They are considered safe for children above 1 year of age and in pregnancy, although use in the first trimester is best avoided. Intestinal obstruction usually responds to conservative management and antihelminthic therapy. Surgery may be required for appendicitis and other gastrointestinal complications.

  **Trichuriasis**

  *Trichuris trichiura*, the whipworm, infects about a billion persons throughout the world, particularly in humid tropical and subtropical environments. Infection is heaviest and most frequent in children. Infections are acquired by ingestion of eggs. The larva hatch in the small intestine and mature in the large bowel to adult worms of about 4 cm in length. The worms do not migrate through tissues.

  Most infected persons are asymptomatic. Heavy infections may be accompanied by abdominal cramps, tenesmus, diarrhea, distention, nausea, and vomiting. The *Trichuris* dysentery syndrome may develop, particularly in malnourished
young children, with findings resembling inflammatory bowel disease including bloody diarrhea and rectal prolapse. Chronic infections in children can lead to iron deficiency anemia, growth retardation, and clubbing of the fingers.

Trichuriasis is diagnosed by identification of characteristic eggs and sometimes adult worms in stools. Concentration techniques are not needed. Eosinophilia is common. Treatment is with albendazole (400 mg/d orally) or mebendazole (200 mg/d orally), for 1–3 days for light infections or 3–7 days for heavy infections, but cure rates are lower than for ascariasis or hookworm infection. The addition of ivermectin (200 mcg/kg orally daily for 1–2 days) to these drugs improves outcomes.

HOOKWORM DISEASE

ESSENTIALS OF DIAGNOSIS

- Transient pruritic skin rash and pulmonary symptoms.
- Anorexia, diarrhea, abdominal discomfort.
- Iron deficiency anemia.
- Characteristic eggs and occult blood in the stool.

General Considerations

Infection with the hookworms *Ancylostoma duodenale* and *Necator americanus* is very common, especially in most tropical and subtropical regions. Both worms are broadly distributed. Prevalence is estimated at about 1 billion, causing approximately 65,000 deaths each year. When eggs are deposited on warm moist soil they hatch, releasing larvae that remain infective for up to a week. With contact, the larvae penetrate skin and migrate in the bloodstream to the pulmonary capillaries. In the lungs, the larvae penetrate into alveoli and then are carried by ciliary action upward to the bronchi, trachea, and mouth. After being swallowed, they reach and attach to the mucosa of the upper small bowel, where they mature to adult worms. *Ancylostoma* infection can also be acquired by ingestion of the larvae in food or water. Hookworms attach to the intestinal mucosa and suck blood. Blood loss is proportionate to the worm burden.

Clinical Findings

A. Symptoms and Signs

Most infected persons are asymptomatic. A pruritic maculopapular rash (ground itch) may occur at the site of larval penetration, usually in previously sensitized persons. Pulmonary symptoms may be seen during larval migration through the lungs, with dry cough, wheezing, and low-grade fever, but these symptoms are less common than with ascariasis. About 1 month after infection, as maturing worms attach to the small intestinal mucosa, gastrointestinal symptoms may develop, with epigastric pain, anorexia, and diarrhea, especially in previously unexposed individuals. Persons chronically infected with large worm burdens may have abdominal pain, anorexia, diarrhea, and findings of marked iron-deficiency anemia and protein malnutrition. Anemia can lead to pallor, weakness, dyspnea, and congestive heart failure, and protein loss can lead to hypoalbuminemia, edema, and ascites. These findings may be accompanied by impairment in growth and cognitive development in children. Infection with the dog hookworm *Ancylostoma caninum* can uncommonly lead to abdominal pain, diarrhea, and eosinophilia, with intestinal ulcerations and regional lymphadenitis.

B. Laboratory Findings

Diagnosis is based on the demonstration of characteristic eggs in feces; concentration techniques are usually not needed. Microcytic anemia, occult blood in the stool, and hypoalbuminemia are common. Eosinophilia is common, especially during worm migration.

Treatment

Treatment is with albendazole (single 400 mg oral dose) or mebendazole (100 mg orally twice daily for 3 days). These drugs are teratogenic, but experience suggests that they are safe in children over 1 year of age and during the second and third trimesters of pregnancy. Occasional adverse effects are diarrhea and abdominal pain. Pyrantel pamoate and levamisole are also effective. Anemia should be managed with iron replacement and, for severe symptomatic anemia, blood transfusion. Mass treatment of children with single doses of albendazole or mebendazole at regular intervals limits worm burdens and the extent of disease and is advocated by the WHO.

STRONGYLOIDIASIS

ESSENTIALS OF DIAGNOSIS

- Transient pruritic skin rash and pulmonary symptoms.
- Anorexia, diarrhea, abdominal discomfort.
- Hyperinfection syndrome in the immunocompromised.
- Larvae detected in stool.
- With hyperinfection, larvae detected in sputum or other fluids.
- Eosinophilia.

General Considerations

Strongyloidiasis is caused by infection with *Strongyloides stercoralis*. Although much less prevalent than ascariasis, trichuriasis, or hookworm infections, strongyloidiasis is nonetheless a significant problem, infecting tens of millions of individuals in tropical and subtropical regions. Infection is also endemic in some temperate regions of North America, Europe, Japan, and Australia. Of particular
importance is the predilection of the parasite to cause severe infections in immunocompromised individuals due to its ability to replicate in humans. A related parasite, *Strongyloides fuelleborni*, infects humans in parts of Africa and New Guinea.

Among nematodes, *S. stercoralis* is uniquely capable of maintaining its full life cycle both within the human host and in soil. Infection occurs when filariform larvae in soil penetrate the skin, enter the bloodstream, and are carried to the lungs, where they escape from capillaries into alveoli, ascend the bronchial tree, and are then swallowed and carried to the duodenum and upper jejunum, where maturation to the adult stage takes place. Females live embedded in the mucosa for up to 5 years, releasing eggs that hatch in the intestines as free rhabditiform larvae that pass to the ground via the feces. In moist soil, these larvae metamorphose into infective filariform larvae. Autoinfection can occur in humans, when some rhabditiform larvae develop into filariform larvae that penetrate the intestinal mucosa or perianal skin, and enter the circulation. The most dangerous manifestation of *S. stercoralis* infection is the hyperinfection syndrome, with dissemination of large numbers of filariform larvae to the lungs and other tissues in immunocompromised individuals. Mortality with this syndrome approaches 100% without treatment and has been about 25% with treatment. The hyperinfection syndrome is seen in patients receiving corticosteroids and other immunosuppressive medications; patients with hematologic malignancies, malnutrition, or alcoholism; or persons with AIDS. The risk seems greatest for those receiving corticosteroids and considering the large number of at risk individuals, the risk in those with AIDS seems relatively low.

### Clinical Findings

#### A. Symptoms and Signs

As with other intestinal nematodes, most infected persons are asymptomatic. An acute syndrome can be seen at the time of infection, with a pruritic, erythematous, maculopapular rash, usually of the feet. These symptoms may be followed by pulmonary symptoms (including dry cough, dyspnea, and wheezing) and eosinophilia after a number of days, followed by gastrointestinal symptoms after some weeks, as with hookworm infections. Chronic infection may be accompanied by epigastric pain, nausea, diarrhea, and anemia. Maculopapular or urticarial rashes of the buttocks, perineum, and thighs, due to migrating larvae, may be seen. Large worm burdens can lead to malabsorption or intestinal obstruction. Eosinophilia is common but may fluctuate.

With hyperinfection, large numbers of larvae can migrate to many tissues, including the lungs, CNS, kidneys, and liver. Gastrointestinal symptoms can include abdominal pain, nausea, vomiting, diarrhea, and more severe findings related to intestinal obstruction, perforation, or hemorrhage. Bacterial sepsis, probably secondary to intestinal ulcerations, is a common presenting finding. Pulmonary findings include pneumonitis, cough, hemoptysis, and respiratory failure. Sputum may contain adult worms, larvae, and eggs. CNS disease includes meningitis and brain abscesses; the CSF may contain larvae. Various presentations can progress to shock and death.

#### B. Laboratory Findings

The diagnosis of strongyloidiasis can be difficult, as eggs are seldom found in feces. Diagnosis is usually based on the identification of rhabditiform larvae in the stool or duodenal contents. These larvae must be distinguished from hookworm larvae, which may hatch after stool collection. Repeated examinations of stool or examination of duodenal fluid may be required for diagnosis because the sensitivity of individual tests is only about 30%. Hyperinfection is diagnosed by the identification of large numbers of larvae in stool, sputum, or other body fluids. An ELISA from the CDC offers about 90% sensitivity and specificity, but cross-reactions with other helminths may occur. Eosinophilia and mild anemia are common, but eosinophilia may be absent with hyperinfection. Hyperinfection may include extensive pulmonary infiltrates, hypoproteinemia, and abnormal liver function studies.

#### C. Screening

It is important to be aware of the possibility of strongyloidiasis in persons with even a distant history of residence in an endemic area, since the infection can be latent for decades. Screening of at-risk individuals for infection is appropriate before institution of immunosuppressive therapy. Screening can consist of serologic tests, with stool examinations in those with positive serologic tests, but consideration of presumptive treatment even if the stool evaluations are negative (see below).

#### Treatment

Full eradication of *S. stercoralis* is more important than with other intestinal helminths due to the ability of the parasite to replicate in humans. The treatment of choice for routine infection is ivermectin (200 mcg orally daily for 1–2 days). This treatment has replaced thiabendazole (25 mg/kg orally twice daily for 3 days), which is relatively poorly tolerated, and albendazole (400 mg orally twice daily for 3 days), which is less effective. For hyperinfection, ivermectin should be administered daily until the clinical syndrome has resolved and larvae have not been identified for at least 2 weeks. Follow-up examinations for larvae in stool or sputum are necessary, with repeat dosing if the infection persists. With continued immunosuppression, eradication may be difficult, and regular repeated doses of antihelminthic therapy (eg, monthly ivermectin) may be required.

### ENTEROBIASIS

#### ESSENTIALS OF DIAGNOSIS

- **Nocturnal perianal pruritus.**
- **Identification of eggs or adult worms on perianal skin or in stool.**
General Considerations

*Enterobius vermicularis*, the pinworm, is a common cause of intestinal infections worldwide, with maximal prevalence in school-age children. Enterobiasis is transmitted person-to-person via ingestion of eggs after contact with the hands or perianal region of an infected individual, food or fomites that have been contaminated by an infected individual, or infected bedding or clothing. Auto-infection also occurs. Eggs hatch in the duodenum and larvae migrate to the cecum. Females mature in about a month, and remain viable for about another month. During this time they migrate through the anus to deposit large numbers of eggs on the perianal skin. Due to the relatively short lifespan of these helminths, continuous reinfection, as in institutional settings, is required, for long-standing infection.

Clinical Findings

A. Symptoms and Signs

Most individuals with pinworm infection are asymptomatic. The most common symptom is perianal pruritus, particularly at night, due to the presence of the female worms or deposited eggs. Insomnia, restlessness, and enuresis are common in children. Perianal scratching may result in excoriation and impetigo. Many mild gastrointestinal symptoms have also been attributed to enterobiasis, but associations are not proven. Serious sequelae are uncommon. Rarely, worm migration results in inflammation or granulomatous reactions of the gastrointestinal or genitourinary tracts. Colonic ulceration and eosinophilic colitis have been reported.

B. Laboratory Findings

Pinworm eggs are usually not found in stool. Diagnosis is made by finding adult worms or eggs on the perianal skin. A common test is to apply clear cellophane tape to the perianal skin, ideally in the early morning, followed by microscopic examination for eggs. The sensitivity of the tape test is reported to be about 50% for a single test and 90% for three tests. Nocturnal examination of the perianal area or gross examination of stools may reveal adult worms, which are about 1 cm in length. Eosinophilia is rare.

Treatment

Treatment is with single oral doses of albendazole (400 mg), mebendazole (100 mg) or pyrantel pamoate (11 mg/kg, to a maximum of 1 g). The dose is repeated in 2 weeks due to frequent reinfection. Other infected family members should be treated concurrently, and treatment of all close contacts may be appropriate when rates of reinfection are high in family, school, or institutional settings. Standard handwashing and hygiene practices are helpful in limiting spread. Perianal scratching should be discouraged. Washing of clothes and bedding should kill pinworm eggs.
numbers of larvae, which are ingested by copepods. Adult worms, which can be up to a meter in length, are gradually extruded. Worm death and disintegration in tissue may provoke a severe inflammatory reaction.

#### Clinical Findings

Patients are usually asymptomatic until the time of worm extrusion. At that time a painful papule develops, with erythema, pruritus, and burning, usually on the lower leg. Multiple lesions may be present. At this time, some patients may also develop a short-lived systemic reaction, which may include fever, urticaria, nausea, vomiting, diarrhea, and dyspnea. The skin lesion vesiculates over a few days, followed by ulceration. The ulcer is tender, often with a visible worm. The worm is then extruded or absorbed over a few weeks, followed by ulcer healing. Secondary infections, including infectious arthritis and tetanus, are common. The disease causes significant disability; lesions commonly prevent walking for a month or more.

Diagnosis follows identification of a typical skin ulcer with a protruding worm. When the worm is not visible, larvae may be identified on smears or seen after immersion in cold water. Eosinophilia is usually present.

#### Treatment

No drug cures the infection, but metronidazole and mebendazole are sometimes used to limit inflammation and facilitate worm removal. Wet compresses may relieve discomfort. Occlusive dressings improve hygiene and limit shedding of infectious larvae. Worms are typically removed by sequentially rolling them out over a small stick. When available, simple surgical procedures can be used to remove worms. Corticosteroid ointments may hasten healing. Topical antibiotics may limit bacterial superinfection.

#### Prevention

Dracunculiasis has proven to be easier to control than most parasitic infections. The disease is prevented by avoidance of contaminated drinking water. This can be accomplished by boiling, chlorination, or filtration through finely woven cloth. A WHO dracunculiasis eradication program, initiated in 1986, has been highly successful.

B. Laboratory Findings

The clinical diagnosis is supported by findings of elevated serum muscle enzymes (creatine kinase, lactate dehydrogenase, aspartate aminotransferase). Serologic tests become positive 3 or more weeks after infection; a variety of techniques are used, including ELISA, immunofluorescence, indirect hemagglutinin, precipitin, and bentonite flocculation assays. Rising antibody titers are highly suggestive of the diagnosis. Muscle biopsy can usually be avoided, but if the diagnosis is uncertain, biopsy of a tender, swollen muscle may identify Trichinella larvae. For maximal yield, biopsy material should be examined histologically, and a portion should be enzymatically digested to release larvae, but evaluation before about 3 weeks after infection may not show muscle larvae.

Treatment

No effective specific therapy for full-blown trichinosis has been identified. However, if infection is suspected early in the course of illness, treatment with mebendazole (2.5 mg/kg orally twice daily) or albendazole (5–7.5 mg/kg orally twice daily) will kill intestinal worms and may limit progression to tissue invasion. Supportive therapy for systemic disease consists of analgesics, antipyretics, bed rest and, in severe illness, corticosteroids. Infection is prevented by cooking to a temperature of at least 71°C for at least 1 minute. Irradiation of meat is also effective in eliminating Trichinella larvae, but freezing is not fully reliable.

ANGIOSTRONGYLIAISIS

Nematodes of rats of the genus Angiostrongylus cause two distinct syndromes in humans. Angiostrongylus cantonensis, the rat lungworm, causes eosinophilic meningoencephalitis, primarily in Southeast Asia and some Pacific islands. Angiostrongylus costaricensis causes gastrointestinal infection. In both diseases, human infection follows ingestion of larvae within slugs or snails (and also crabs or prawns for A cantonensis) or on material contaminated by these organisms. Since the parasites are not in their natural hosts, they cannot complete their life cycles, but they can cause disease after migrating to the brain or gastrointestinal tract.

Clinical Findings

A. A cantonensis Infection

The disease appears to be caused primarily by worm larvae migrating through the CNS and an inflammatory response to dying worms. After an incubation period of 1 day to 2 weeks, presenting symptoms and signs include headache, stiff neck, nausea, vomiting, cranial nerve abnormalities, and paresthesias. Most cases resolve spontaneously after 2–8 weeks, but serious sequelae and death have been reported. The diagnosis is strongly suggested by the finding of eosinophilic CSF pleocytosis (leukocytosis with over 10% eosinophils) in a patient with a history of travel to an endemic area. Peripheral eosinophilia may not be present. A cantonensis larvae have rarely been recovered from the CSF and the eyes.

B. A costaricensis Infection

Parasites penetrate ileocecal vasculature and develop into adults, which lay eggs, but do not complete their life cycle. Disease is due to an inflammatory response to dying worms in the intestinal tract, with an eosinophilic granulomatous response, at times including vasculitis and ischemic necrosis. Common findings are abdominal pain, vomiting, and fever. Pain is most commonly localized to the right lower quadrant, and a mass may be appreciated, all mimicking appendicitis. Symptoms may recur over months. Uncommon findings are intestinal perforation or obstruction, or disease due to migration of worms to other sites. Many cases are managed surgically, usually for suspected appendicitis. Biopsy of inflamed intestinal tissue may show worms localized to mesenteric arteries and eosinophilic granulomas.

Treatment

Antihelminthic therapy may be harmful for A cantonensis infection, since responses to dying worms may worsen with therapy. If antihelminthic treatment is to be used, albendazole is probably the best choice. Corticosteroids have been used in severe cases, and these are probably appropriate if antihelminthics are provided. It is not known if antihelminthic therapy is helpful for A costaricensis infection.

HNOSTOMIASIS

A number of species of Gnathostoma, which are parasites of carnivores, can occasionally infect humans. Most cases have been seen in Southeast Asia, but the disease has also been described in many other areas. Eggs shed in the feces of mammals are ingested by marine crustaceans, which are then ingested by fish, frogs, snakes, or mammals. Larvae then encyst in muscles. Human infection follows eating undercooked fish, shellfish, chicken, or pork and can also be transmitted by ingesting copepods in contaminated water. After ingestion, larvae cannot complete development in humans, but rather migrate through tissues. Acute gastrointestinal symptoms, including nausea, vomiting, abdominal pain, and fever, may develop soon after infection and persist for 2–3 weeks. The disease may then progress.
PROTOZOAL & HELMINTHIC INFECTIONS

TOXOCARIASIS

General Considerations

The dog roundworm *Toxocara canis*, the cat roundworm *Toxocara cati*, and less commonly other helminths may cause visceral larva migrans. *T. canis* is highly prevalent in dogs. Humans are infected after ingestion of eggs in material contaminated by dog or other feces. With *T. canis*, infection is spread principally by puppies and lactating females, and the eggs must be on the ground for several weeks before they are infectious. After ingestion by humans, larvae migrate to various tissues but cannot complete their life cycle.

Clinical Findings

Visceral larva migrans is seen principally in young children. Most infections are asymptomatic. The most commonly involved organs are the liver and lungs. Presentations include cough, fever, wheezing, hepatomegaly, splenomegaly, lymphadenopathy, pulmonary infiltrates, and eosinophilia. Involvement of the CNS can occur rarely, leading to eosinophilic meningitis and other abnormalities. Ocular larva migrans is a distinct syndrome, usually in children older than is typical for visceral larva migrans. Children present with visual deficits, pain, and a retinal mass, which can be confused with retinoblastoma. *Baylisascaris procyonis*, a roundworm of raccoons, can rarely cause visceral larva migrans in humans, with typically more severe manifestations than those with *T. canis*, including eosinophilic meningitis and eye disease.

The diagnosis of visceral larva migrans is suggested by the finding of eosinophilia in a child with hepatomegaly or other signs of the disease, especially with a history of exposure to puppies. The diagnosis is confirmed by the identification of larvae in a biopsy of infected tissue, usually performed when other diseases are suspected. Serologic tests may be helpful; an available ELISA was estimated to have 78% sensitivity and 92% specificity. Most patients recover without specific therapy, although symptoms may persist for months.

Treatment

Treatment with antihelminthics or corticosteroids may be considered in severe cases. No drugs have been proven to be effective, but albendazole (400 mg orally twice daily for 5 days), mebendazole, thiabendazole, diethylcarbamazine, and ivermectin have been used, and albendazole has been recommended as the treatment of choice.

CUTANEOUS LARVA MIGRANS (Creeping Eruption)

Cutaneous larva migrans is caused principally by larvae of the dog and cat hookworms, *Ancylostoma braziliense* and *A. caninum*. Other animal hookworms, gnathostomiasis, and strongyloidiasis may also cause this syndrome. Infections are common in warm areas, including the southeastern United States. They are most common in children. The disease is caused by the migration of worms through skin; the non-human parasites cannot complete their life cycles, so only cause cutaneous disease.

Clinical Findings

Intensely pruritic erythematous papules develop, usually on the feet or hands, followed within a few days by serpiginous tracks marking the course of the parasite, which may travel several millimeters per day (Figure 35–8). Several tracks may be present. The process may continue for weeks, with lesions becoming vesiculated, encrusted, or secondarily infected. Systemic symptoms or eosinophilia are uncommon.

The diagnosis is based on the characteristic appearance of the lesions. Biopsy is usually not indicated.

Treatment

Without treatment, the larvae eventually die and are absorbed. Mild cases do not require treatment. Thiabendazole (10% aqueous suspension) can be applied topically three times daily for 5 or more days. Systemic therapy with albendazole (400 mg orally once or twice daily for 3–5 days) or ivermectin (200 mcg/kg orally single dose) is highly effective.
consideration of other diagnoses, eosinophilic inflammatory lesions and the invading worms are found.

**Treatment**

Specific therapy is not indicated, but endoscopic worm removal hastens recovery. The parasites are killed by cooking or deep freezing fish.

**FILARIASIS**

**Lymphatic Filariasis**

**Essentials of Diagnosis**

- Episodic attacks of lymphangitis, lymphadenitis, and fever.
- Chronic progressive swelling of extremities and genitals; hydrocele; chyluria; lymphedema.
- Microfilariae in blood, chyluria, or hydrocele fluid; positive serologic tests.

Lymphatic filariasis is caused by three filarial nematodes: *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*, and is among the most important parasitic diseases of man. Approximately 120 million people are infected with these organisms in tropical and subtropical countries, about a third of these suffer clinical consequences of the infections, and many are seriously disfigured. *W bancrofti* causes about 90% of episodes of lymphatic filariasis. It is transmitted by *Culex*, *Aedes*, and *Anopheles* mosquitoes and is widely distributed in the tropics and sub-tropics, including subsaharan Africa, Southeast Asia, the western Pacific, India, South America, and the Caribbean. *B malayi* is transmitted by *Mansonia* and *Anopheles* mosquitoes and is endemic in parts of China, India, Southeast Asia, and the Pacific. *B timori* is found only in islands of southeastern Indonesia. *Mansonella* are filarial worms transmitted by midges and other insects in Africa and South America.

Humans are infected by the bites of infected mosquitoes. Larvae then move to the lymphatics and lymph nodes, where they mature to thread-like adult worms, and then can persist for many years. The adult worms produce large numbers of microfilariae, which are released into the circulation, and infective to mosquitoes, particularly at night (except for the South Pacific, where microfilaremia peaks during daylight hours).
Clinical Findings

A. Symptoms and Signs

Many infections remain asymptomatic despite circulating microfilariae. Clinical consequences of filarial infection are principally due to inflammatory responses to developing, mature, and dying worms. The initial manifestation of infection is often acute lymphangitis, with fever, painful lymph nodes, edema, and inflammation spreading peripherally from involved lymph nodes (in contrast to bacterial lymphangitis, which spreads centrally). Lymphangitis and lymphadenitis of the upper and lower extremities is common (Figure 35–9); genital involvement, including epididymitis and orchitis, with scrotal pain and tenderness, occurs principally only with *W. bancrofti* infection. Acute attacks of lymphangitis last for a few days to a week and may recur a few times per year. Filarial fevers may also occur without lymphatic inflammation.

The most common chronic manifestation of lymphatic filariasis is swelling of the extremities or genitals due to chronic lymphatic inflammation and obstruction. Extremities become increasingly swollen, with a progression over time from pitting edema, to nonpitting edema, to sclerotic changes of the skin that are referred to as elephantiasis. Genital involvement, particularly with *W. bancrofti*, occurs more commonly in men, progressing from painful epididymitis to hydroceles that are usually painless but can become very large, with inguinal lymphadenopathy, thickening of the spermatic cord, scrotal lymphedema, thickening and fissuring of the scrotal skin, and occasionally chyluria. Lymphedema of the female genitalia and breasts may also occur.

Tropical pulmonary eosinophilia is a distinct syndrome principally affecting young adult males with either *W. bancrofti* or *B. malayi* infection but typically without microfilaraemia. This syndrome is characterized by asthma-like symptoms, with cough, wheezing, dyspnea, and low-grade fevers, usually at night. Without treatment, tropical pulmonary eosinophilia can progress to interstitial fibrosis and chronic restrictive lung disease. *Mansonella* can inhabit serous cavities, the retroperitoneum, the eye, or the skin, and cause abnormalities related to inflammation at these sites.

B. Laboratory Findings

The diagnosis of lymphatic filariasis is strongly suggested by characteristic findings of lymphangitis or lymphatic obstruction in persons with risk factors for the disease. The diagnosis is confirmed by finding microfilariae, usually in blood, but this may be difficult. In addition, microfilariae may be absent, especially early in the disease progression (first 2–3 years) or with chronic obstructive disease. To increase yields, blood samples are obtained at about midnight in most areas, but not in the South Pacific, where microfilaraemia is diurnal. Smears are evaluated by wet mount to identify motile parasites and by Giemsa staining; these examinations can be delayed until the following morning, with storage of samples at room temperature. Of note, the periodicity of microfilaraemia is variable, and daytime samples may yield positive results. Microfilariae may also be identified in hydrocele fluid or chylous urine. Eosinophilia is usually absent, except during acute inflammatory syndromes. Available serologic tests, including bentonite flocculation, indirect hemagglutination, ELISA, and indirect fluorescent antibody tests, may be helpful but cannot distinguish between past and active infections. Rapid antigen tests with sensitivity and specificity over 90% are available, and these are increasingly used to guide control programs. Adult worms may also be found in lymph node biopsy specimens (although biopsy is not usually clinically indicated) or by ultrasound of a scrotal hydrocele or lymphedematous breast. When microfilaraemia is lacking, especially if sophisticated techniques are not available, diagnoses may need to be made on clinical grounds alone.

Treatment & Control

A. Drug Treatment

Treatment is somewhat controversial, as no drug can fully control or reverse the disease, and treatment may cause serious acute inflammatory symptoms. Diethylcarbamazine is the drug of choice, but it cannot cure infections due to its limited action against adult worms. Asymptomatic infection and acute lymphangitis are treated with this drug (2 mg/kg orally three times daily) for 10–14 days, leading to a marked decrease in microfilaraemia. Therapy may be accompanied by allergic symptoms, including fever, headache, malaise, hypotension, and bronchospasm, probably due to release of antigens from dying worms. For this reason, treatment courses may begin with a lower dosage, with escalation over the first 4 days of treatment. Single annual doses of diethylcarbamazine (6 mg/kg orally), alone or with ivermectin (400 mcg/kg orally) or albendazole (400 mg orally) may be as effective as longer courses of diethylcarbamazine. When onchocerciasis or loiasis is suspected, it may be appropriate to withhold diethylcarbamazine to avoid severe reactions to dying microfilariae; rather, ivermectin plus albendazole may
be given, although these drugs are less active than diethylcarbamazine against adult worms. Appropriate management of advanced obstructive disease is uncertain. Drainage of hydroceles provides symptomatic relief, although they will recur. Therapy with diethylcarbamazine cannot reverse chronic lymphatic changes but is typically provided to lower worm burdens. An interesting approach under study is to treat with doxycycline (100–200 mg/d orally for 4–6 weeks), which kills obligate intracellular Wolbachia bacteria, leading to death of adult filarial worms. Doxycycline was also effective at controlling *Mansonella perstans* infection, which does not respond well to standard antifilarial drugs. Secondary bacterial infections must be treated. Surgical correction may be helpful in some cases.

**B. Disease Control**

Avoidance of mosquitoes is a key measure; preventive measures include the use of screens, bed nets (ideally treated with insecticide), and insect repellents. Community-based treatment with single annual doses of effective drugs offers a highly effective means of control. The current WHO strategy for control includes mass treatment of at risk communities with single annual doses of diethylcarbamazine plus albendazole or, for areas with onchocerciasis, albendazole plus ivermectin; in some circumstances, more frequent dosing offers improved control.

**ESSENTIALS OF DIAGNOSIS**

- Severe pruritus; skin excoriations, thickening, and depigmentation; and subcutaneous nodules.
- Conjunctivitis progressing to blindness.
- Microfilariae in skin snips and on slit-lamp examination; adult worms in subcutaneous nodules.

**General Considerations**

Onchocerciasis, or river blindness is caused by *Onchocerca volvulus*. An estimated 18 million persons are infected, of whom 3–4 million have skin disease, 500,000 have severe visual impairment, and 300,000 are blinded. Over 99% of infections are in sub-Saharan Africa, especially the West African savanna, with about half of cases in Nigeria and Congo. In some hyperendemic African villages, close to 100% of individuals are infected, and at least 50% or more of the population is blind. The disease is also prevalent in the southwestern African peninsula and Latin America, including southern Mexico, Guatemala, Venezuela, Colombia, Ecuador, and northwestern Brazil. Onchocerciasis is transmitted by *simulium* flies (blackflies). These insects breed in fast-flowing streams and bite during the day.

After the bite of an infected blackfly, larvae are deposited in the skin, where adults develop over 6–12 months. Adult worms live in subcutaneous connective tissue or muscle nodules for a decade or more. Microfilariae are released from the nodules and migrate through subcutaneous and ocular tissues. Disease is due to responses to worms and to intracellular Wolbachia bacteria.

**Clinical Findings**

**A. Symptoms and Signs**

After an incubation period of up to 1–3 years, the disease typically produces an erythematous, papular, pruritic rash, which may progress to chronic skin thickening and depigmentation. Itching may be severe and unresponsive to medications, such that more disability-adjusted life years are lost to onchocercal skin problems than to blindness. Numerous firm, nontender, movable subcutaneous nodules of about 0.5–3 cm, which contain adult worms, may be present. Due to differences in vector habits, these nodules are more commonly on the lower body in Africa but on the head and upper body in Latin America. Inginal and femoral lymphadenopathy is common, at times resulting in a “hanging groin,” with lymph nodes hanging within a sling of atrophic skin. Patients may also have systemic symptoms, with weight loss and musculoskeletal pain.

The most serious manifestations of onchocerciasis involve the eyes. Microfilariae migrating through the eyes elicit host responses that lead to pathology. Findings include punctate keratitis and corneal opacities, progressing to sclerosing keratitis and blindness. Iridocyclitis, glaucoma, choroiditis, and optic atrophy may also lead to vision loss. The likelihood of blindness after infection varies greatly based on geography, with the risk greatest in savanna regions of West Africa.

**B. Diagnostic Testing**

The diagnosis is made by identifying microfilariae in skin snips, by visualizing microfilariae in the cornea or anterior chamber by slit-lamp examination, by identification of adult worms in a biopsy or aspirate of a nodule or, uncommonly, by identification of microfilariae in urine. Skin snips from the iliac crest (Africa) or scapula (Americas) are allowed to stand in saline for 2–4 hours or longer, and then examined microscopically for microfilariae. Deep punch
biopsies are not needed, and if suspicion persists after a skin snip is negative, the procedure should be repeated. Ultrasound may identify characteristic findings suggestive of adult worms in skin nodules. When the diagnosis remains difficult, the Mazzotti test can be used. In this test, a 50-mg dose of diethylcarbamazine is given. A positive test, with exacerbation of skin rash and pruritus, usually within 3 hours, is highly suggestive of the diagnosis. This test should only be used in suspected lightly infected patients (after other tests are negative), as this treatment can elicit severe skin and eye reactions in heavily infected individuals. A related and safer test using topical diethylcarbamazine is available in some areas. Eosinophilia is a common, but inconsistent finding. Serologic tests are poorly standardized, non-specific, and generally unhelpful, as in endemic areas positivity is not indicative of acute disease.

### Treatment & Control

The treatment of choice is ivermectin, which has replaced diethylcarbamazine due to a much lower risk of severe reactions to therapy. Ivermectin kills microfilarema, but not adult worms, so disease control requires repeat administrations. Treatment is with a single oral dose of 150 mcg/mL, but schedules for re-treatment have not been standardized. One regimen is to treat every 3 months for 1 year, followed by treatment every 6–12 months for the suspected lifespan of adult worms (about 15 years). Treatment results in marked reduction in numbers of microfilariae in the skin and eyes, although its impact on the progress of visual loss remains uncertain. Toxicities of ivermectin are generally mild; fever, pruritus, urticaria, myalgias, edema, hypotension, and tender lymphadenopathy may be seen, presumably due to reactions to dying worms. Ivermectin should be used with caution in patients also at risk for loiasis, since it can elicit severe reactions including encephalopathy. In patients with severe skin findings not controlled by ivermectin, therapy with suramin may be considered. This is the only drug known to kill adult worms, but it is very toxic. As with other filarial infections, doxycycline acts against *O. volvulus* by killing intracellular Wolbachia bacteria. A course of 100 mg/day for 6 weeks kills the bacteria and prevents parasite embryogenesis for at least 18 months. Doxycycline is under study for onchocerciasis control but has no clear role in treatment of individual affected patients. Protection against onchocerciasis includes avoidance of biting flies. Major efforts are underway to control insect vectors in Africa. In addition, mass distribution of ivermectin for intermittent administration at the community level is ongoing, and the prevalence of severe skin and eye disease is decreasing.

rule out loiasis before administration of ivermectin for the control of other filarial infections.

**Treatment**

The treatment of choice is diethylcarbamazine, which eliminates microfilariae and has some activity against adult worms. Treatment with 8–10 mg/kg/d orally for 21 days is curative in about 50% of amicrofilaremic patients, and repeat courses increase efficacy. Mild side effects are common with therapy, including fever, pruritus, arthralgias, nausea, diarrhea, and Calabar swellings. These symptoms may be lessened by administration of antihistamines or corticosteroids. Patients with large worm burdens are at greater risk for serious complications of therapy, including kidney injury, shock, encephalitis, coma, and death. Treatment with ivermectin, which is highly active against microfilariae, but not adult worms, also entails a high risk of severe reactions. To attempt to avoid these sequelae, pretreatment with corticosteroids and antihistamines, and escalating dosage of diethylcarbamazine have been used, but this strategy does not prevent encephalitis. The circulating parasite load that indicates particular risk for severe complications with therapy has been estimated at 2500/mL or greater. Strategies to treat patients with high parasite loads include (1) no treatment; (2) apheresis, if available, to remove microfilariae prior to therapy with diethylcarbamazine; or (3) therapy with albendazole, which appears to be well tolerated due to its slow antiparasitic effects, prior to therapy with diethylcarbamazine or ivermectin.

Mycotic Infections

Samuel A. Shelburne, MD, PhD
Richard J. Hamill, MD

Fungal infections have assumed an increasingly important role as use of broad-spectrum antimicrobial agents has increased and the number of immunodeficient patients has grown. Some pathogens (eg, Cryptococcus, Candida, Pneumocystis, Fusarium) rarely cause serious disease in normal hosts. Other endemic fungi (eg, Histoplasma, Coccidioides, Paracoccidioides) commonly cause disease in normal hosts but tend to be more aggressive in immunocompromised ones. Superficial mycoses are discussed in Chapter 6.

Successful management of most systemic fungal infections requires knowledge of the natural history of these diseases as well as familiarity with the unique pharmacokinetics, adverse effects, and drug interactions of the various therapeutic agents. Furthermore, most affected individuals usually have significant underlying illnesses. Consequently, clinicians with extensive experience in the management of these disorders should be routinely consulted.

CANDIDIASIS

ESSENTIALS OF DIAGNOSIS

- Common normal flora but opportunistic pathogen.
- Gastrointestinal mucosal disease, particularly esophagitis, most common.
- Intravenous catheter-associated fungemia occurs in patients who have sustained cutaneous or mucosal injury, undergone instrumentation, or received broad-spectrum antibiotics.

General Considerations

Candida albicans can be cultured from the mouth, vagina, and feces of most people. Cutaneous and oral lesions are discussed in Chapters 6 and 8, respectively. The risk factors for invasive candidiasis include prolonged neutropenia, recent abdominal surgery, broad-spectrum antibiotic therapy, advanced chronic kidney disease, and the presence of intravascular catheters (especially when providing total parenteral nutrition). Cellular immunodeficiency predisposes to mucocutaneous disease. When no other underlying cause is found, persistent oral or vaginal candidiasis should arouse a suspicion of HIV infection.

Clinical Findings

A. Mucosal Candidiasis

Esophageal involvement is the most frequent type of significant mucosal disease. Presenting symptoms include substernal odynophagia, gastroesophageal reflux, or nausea without substernal pain. Oral candidiasis, though often associated, is not invariably present. Diagnosis is best confirmed by endoscopy with biopsy and culture.

Vulvovaginal candidiasis occurs in an estimated 75% of women during their lifetime. Risk factors include pregnancy, uncontrolled diabetes mellitus, broad-spectrum antimicrobial treatment, corticosteroid use, and HIV infection. Symptoms include acute vulvar pruritus, burning vaginal discharge, and dyspareunia.

B. Candidal Funguria

Most cases of candidal funguria are asymptomatic and represent specimen contamination or bladder colonization. However, signs and symptoms of true Candida urinary tract infections are indistinguishable from bacterial urinary tract infections and can include urgency, hesitancy, fever, chills, or flank pain.

C. Disseminated Candidiasis

The diagnosis of disseminated Candida infection is problematic because Candida species are often isolated from mucosal sites in the absence of invasive disease while blood cultures are positive only 50% of the time in disseminated infection. Serologic tests have not proved useful for distinguishing colonization from invasive disease. Isolation of Candida species from blood cultures may represent a benign, self-limited process, but until proven otherwise it should be considered a sign of serious, complicated disease.
Another form of invasive disease is hepatosplenic candidiasis. This results from aggressive chemotherapy and prolonged neutropenia in patients with underlying hematologic cancers. Typically, fever and variable abdominal pain present weeks after chemotherapy, when neutrophil counts have recovered. Blood cultures are generally negative. Hepatic enzymes reveal an alkaline phosphatase elevation that may be marked.

D. Candidal Endocarditis

Candidal endocarditis is a rare infection that is most frequently associated with exposure to a healthcare setting. Candidal endocarditis occurs with increased frequency on prosthetic valves in the first few months following surgery. The diagnosis is established definitively by culturing *Candida* from emboli or from vegetations at the time of valve replacement.

**Treatment**

A. Mucosal Candidiasis

Therapy of *esophageal candidiasis* depends on the severity of disease. If patients are able to swallow and take adequate amounts of fluid orally, fluconazole, 100 mg/d (or itraconazole solution, 10 mg/mL, 200 mg/d), for 10–14 days usually suffices. In the individual who is more ill or in whom esophagitis has developed while taking fluconazole, options include oral or intravenous voriconazole, 200 mg twice daily; intravenous amphotericin B, 0.3 mg/kg/d; intravenous caspofungin, 50 mg/d; intravenous anidulafungin, 100 mg on day 1, then 50 mg/d; or intravenous micafungin, 150 mg/d. Relapse is common with all agents when there is underlying HIV infection without adequate immune reconstitution.

Various topical azole preparations (eg, clotrimazole, 100 mg vaginal tablet for 7 days, or miconazole, 200 mg vaginal suppository for 3 days) are effective against *vulvovaginal candidiasis*. One 130 mg oral dose of fluconazole has been shown to have equivalent efficacy with better patient acceptance. Disease recurrence is common but can be decreased with weekly fluconazole therapy (150 mg weekly).

B. Candidal Funguria

Candidal funguria frequently resolves with discontinuance of antibiotics or removal of bladder catheters. Clinical benefit from treatment of asymptomatic candiduria has not been demonstrated, but persistent funguria should raise the suspicion of disseminated infection. When symptomatic funguria persists, oral fluconazole, 200 mg/d for 7–14 days, can be used. Newer generation azoles (eg, voriconazole) and echinocandins are not considered standard therapy for candidal urinary tract infections due to low levels of active drug in the urine.

C. Disseminated Candidiasis

The decision to treat for disseminated *Candida* when organisms are isolated from urine or sputum (or both) needs to be individualized for each patient. A randomized trial of empiric fluconazole for patients at high risk for, but not proven to have, disseminated candidiasis showed no clinical benefit compared with placebo.

The 2009 guidelines for treatment of invasive candidiasis recommend fluconazole (loading dose of 800 mg [12 mg/kg] intravenously, then 400 mg [6 mg/kg] intravenously daily) for less critically ill patients who have had no recent azole exposure. For patients with moderately severe to severe illness or for patients who have had recent azole exposure, an echinocandin such as caspofungin (loading dose of 70 mg intravenously once, then 50 mg intravenously daily), micafungin (100 mg intravenously daily), anidulafungin (loading dose of 200 mg intravenously once, then 100 mg intravenously daily) is favored. Therapy for candidemia should be continued for 2 weeks after the last positive blood culture and resolution of symptoms and signs of infection. A dilated fundoscopic examination is recommended for all patients with candidemia to exclude endophthalmitis and repeat blood cultures should be drawn to demonstrate organism clearance. Once patients have become clinically stable, parenteral therapy can be discontinued and oral fluconazole, 200–800 mg orally given as one or two doses daily, is used to complete treatment for isolates known to be or likely to be susceptible to fluconazole. Removal or exchange of intravascular catheters is generally recommended for non-neutropenic patients, since this may decrease the duration of candidemia and overall mortality, which approaches 30%.

Non-*albicans* species of *Candida* account for over 50% of clinical bloodstream isolates and often have resistance patterns that are different from *C. albicans*. An echinocandin is recommended for treatment of *Candida glabrata* infection with a transition to oral fluconazole or voriconazole reserved for patients whose isolates are known to be susceptible to these agents. Similarly, *Candida krusei* is generally fluconazole-resistant and should be treated with a new alternative agent, such as echinocandin or voriconazole. Fluconazole is the treatment of choice for *Candida parapsilosis* due to possible echinocandin resistance in such isolates.

Treatment for hepatosplenic candidiasis is with fluconazole, 400 mg orally daily, or a lipid formulation of amphotericin B should be given until clinical and radiographic improvement occurs.

D. Candidal Endocarditis

Amphotericin, either in a lipid or standard formulation, has long been considered the optimal therapy for candidal endocarditis, given in a dosage of 0.5–1 mg/kg/d intravenously, and can be given along with 5-flucytosine (25 mg/kg four times daily). Alternatively, fluconazole can be added to amphotericin B at dosages greater than 400 mg/d, followed by long-term oral suppressive therapy. Aggressive surgical intervention appears to be beneficial. There are now more data regarding the usefulness of echinocandins in this setting.

In high-risk patients undergoing induction chemotherapy, bone marrow transplantation, or liver transplantation, prophylaxis with antifungal agents has been shown to prevent invasive fungal infections although the effect on mortality and the preferred agent remain debated.
Histoplasmosis is caused by *Histoplasma capsulatum*, a dimorphic fungus that has been isolated from soil contaminated with bird or bat droppings in endemic areas (central and eastern United States, eastern Canada, Mexico, Central America, South America, Africa, and southeast Asia). Infection presumably takes place by inhalation of conidia. These convert into small budding cells that are engulfed by phagocytes in the lungs. The organism proliferates and undergoes lymphohematogenous spread to other organs.

### Clinical Findings

#### A. Symptoms and Signs

Most cases of histoplasmosis are asymptomatic or mild and thus go unrecognized. Past infection is recognized by pulmonary and splenic calcification noted on incidental radiographs. Symptomatic infection may present with mild influenza-like illness, often lasting 1–4 days. Moderately severe infections are frequently diagnosed as atypical pneumonia. These patients have fever, cough, and mild central chest pain lasting 5–15 days.

Clinically evident infections occur in several forms: (1) **Acute histoplasmosis** frequently occurs in epidemics, often when soil containing infected bird or bat droppings is disturbed. It is a relatively severe disease manifested by marked prostration, fever, and comparatively few pulmonary complaints even when radiographs show diffuse pneumonia. The illness may last from 1 week to 6 months but is almost never fatal. (2) **Progressive disseminated histoplasmosis** is commonly seen in patients with underlying HIV infection (with CD4 cell counts usually < 100 cells/mcL) or other conditions causing immunosuppression. Disseminated histoplasmosis has been more frequently reported in patients from endemic areas taking tumor necrosis factor (TNF)-blocking agents. It is characterized by fever and multiple organ system involvement. Chest radiographs may show a miliary pattern. Presentation may be fulminant, simulating septic shock, with death ensuing rapidly unless treatment is provided. Symptoms usually consist of fever, dyspnea, cough, loss of weight, and prostration. Ulcers of the mucous membranes of the oropharynx may be present. The liver and spleen are nearly always enlarged, and all the organs of the body are involved, particularly the adrenal glands, though this infrequently results in adrenal insufficiency. Gastrointestinal involvement may mimic inflammatory bowel disease. (3) **Subacute/chronic progressive pulmonary histoplasmosis** is usually seen in older patients with various lesions including apical cavities, infiltrates, and nodules found on radiographs. (4) **Chronic progressive disseminated histoplasmosis** usually occurs in middle-aged to elderly men with no known condition causing immunosuppression. Presentation is similar to acute disseminated histoplasmosis except for the chronicity of symptoms; it can result in death if not treated. (5) **Complications of pulmonary histoplasmosis** include granulomatous mediastinitis characterized by persistently enlarged mediastinal lymph nodes and fibrosing mediastinitis in which an excessive fibrotic response to *Histoplasma* infection results in compromise of the great vessels.

### B. Laboratory Findings

Most patients with progressive pulmonary disease show anemia of chronic disease. Bone marrow involvement may be prominent in disseminated forms with occurrence of pancytopenia. Alkaline phosphatase and marked lactate dehydrogenase (LDH) and ferritin elevations are also common as are mild elevations of serum aspartate aminotransferase, although alanine aminotransferase is often normal.

With pulmonary involvement, sputum culture is rarely positive except in chronic disease; antigen testing of bronchoalveolar lavage fluid may be helpful in acute disease. The combination of a urine and serum antigen assay has an 83% sensitivity for the diagnosis of acute pulmonary histoplasmosis. Blood or bone marrow cultures from immunocompromised patients with acute disseminated disease are positive more than 80% of the time but may take several weeks for growth. The urine antigen assay has a sensitivity of > 90% for disseminated disease in immunocompromised patients and a declining titer can be used to follow response to therapy.

### Treatment

For progressive localized disease and for mild to moderately severe nonmeningeal disseminated disease in immunocompetent or immunocompromised patients,
itraconazole, 200–400 mg/d orally divided into two doses, is the treatment of choice with an overall response rate of approximately 80%. The oral solution is better absorbed than the capsule formulation, which requires gastric acid for absorption. Duration of therapy ranges from weeks to several months depending on the severity of illness. Intravenous amphotericin B formulations are used in patients with more severe illness such as meningitis, with guidelines favoring the use of liposomal or lipid complex amphotericin formulations at a dose of 3 mg/kg/d over amphotericin B deoxycholate. Patients with AIDS-related histoplasmosis require lifelong suppressive therapy with itraconazole, 200–400 mg/d orally, although secondary prophylaxis may be discontinued if immune reconstitution occurs in response to antiretroviral therapy. There is no clear evidence that antifungal or anti-inflammatory agents are of benefit for patients with granulomatous mediastinitis or fibrosing mediastinitis although oral itraconazole is often used. Reported outcomes in patients with fibrosing mediastinitis treated with either surgical procedures or nonsurgical intravascular interventions appear to be relatively good.

Less than 1% of immunocompetent persons show dissemination, but among these patients, the mortality rate is high.

In HIV-infected people in endemic areas, coccidioidomycosis is a common opportunistic infection. In these patients, disease manifestations range from focal pulmonary infiltrates to widespread miliary disease with multiple organ involvement and meningitis; severity is inversely related to the extent of control of the HIV infection.

► Clinical Findings

A. Symptoms and Signs

Symptoms of primary coccidioidomycosis occur in about 40% of infections. Symptom onset (after an incubation period of 10–30 days) is usually that of a respiratory tract illness with fever and occasionally chills. Coccidioidomycosis is a common, frequently unrecognized, etiology of community-acquired pneumonia in endemic areas.

Arthralgia accompanied by periarticular swelling, often of the knees and ankles, is common. Erythema nodosum may appear 2–20 days after onset of symptoms. Persistent pulmonary lesions, varying from cavities and abscesses to parenchymal nodular densities or bronchiectasis, occur in about 5% of diagnosed cases.

Disseminated disease occurs in about 0.1% of white and 1% of nonwhite patients. Filipinos and blacks are especially susceptible, as are pregnant women of all races. Any organ may be involved. Pulmonary findings usually become more pronounced, with mediastinal lymph node enlargement, cough, and increased sputum production. Lung abscesses may rupture into the pleural space, producing an empyema. These may also extend to bones and skin, and pericardial and myocardial involvement has been occasionally observed. Fungemia may occur and is characterized clinically by a diffuse miliary pattern on chest radiograph and by early death. The course may be particularly rapid in immunosuppressed patients. Clinicians caring for immunosuppressed patients in endemic areas need to consider that patients may be latently infected.

Meningitis occurs in 30–50% of cases of dissemination. Subcutaneous abscesses and verrucous skin lesions are especially common in fulminating cases. Lymphadenitis may occur and may progress to suppuration. HIV-infected persons with disseminated disease have a higher incidence of miliary infiltrates, lymphadenopathy, and meningitis, but skin lesions are uncommon.

B. Laboratory Findings

In primary coccidioidomycosis, there may be moderate leukocytosis and eosinophilia. Serologic testing is useful for both diagnosis and prognosis. The immunodiffusion tube precipitin test and enzyme-linked immunosorbent assay (ELISA) detect IgM antibodies and are both useful for diagnosis early in the disease process. Historically, a persistent rising IgG complement fixation titer (≥ 1:16) has been considered suggestive of disseminated disease; in addition, complement fixation titers can be used to assess the adequacy of therapy. Serum complement fixation titer may be

► General Considerations

Coccidioidomycosis should be considered in the diagnosis of any obscure illness in a patient who has lived in or visited an endemic area.

Infection results from the inhalation of arthroconidia of *Coccidioides immitis* or *C posadasii*; both organisms are molds that grow in soil in certain arid regions of the southwestern United States, in Mexico, and in Central and South America.
low when there is meningitis but no other disseminated disease. In patients with HIV-related coccidioidomycosis, the false-negative rate may be as high as 30%.

Demonstrable complement-fixing antibodies in spinal fluid are diagnostic of coccidioidal meningitis. These are found in over 90% of cases. Spinal fluid findings include increased cell count with lymphocytosis and reduced glucose. Spinal fluid culture is positive in approximately 30% of meningitis cases. Spheres filled with endospores may be found in biopsy specimens of soft tissues and bone; though they are not infectious, they convert to the highly contagious arthroconidia when grown in culture media. Blood cultures are rarely positive.

C. Imaging

Radiographic findings vary, but patchy, nodular pulmonary infiltrates and thin-walled cavities are most common. Hilar lymphadenopathy may be visible and is seen in localized disease; mediastinal lymphadenopathy suggests dissemination. There may be pleural effusions and lytic lesions in bone with accompanying complicated soft-tissue collections.

Treatment

General symptomatic therapy is given as needed for disease limited to the chest with no evidence of progression. For progressive pulmonary or extrapulmonary disease, amphotericin B intravenously is used although oral azoles may be used for mild cases (see Chapter 30). Duration of therapy is determined by a declining complement fixation titer and a favorable clinical response. For meningitis, treatment usually is with high-dose oral fluconazole (400–800 mg/d, or higher) although lumbar or cisternal intrathecal administration of amphotericin B daily in increasing doses up to 1–1.5 mg/d is used initially by some physicians or in cases refractory to fluconazole. Systemic therapy with amphotericin B, 0.6 mg/kg/d intravenously, is generally given concurrently with intrathecal therapy but is not sufficient alone for the treatment of meningeval disease. Voriconazole or posaconazole may be alternatives to intrathecal amphotericin B in patients who do not respond to fluconazole. Once the patient is clinically stable, oral therapy with an azole, usually with fluconazole (400 mg daily) and given lifelong, is the recommended alternative to intrathecal amphotericin B therapy.

Itraconazole, 400 mg orally daily divided into two doses, or fluconazole, 200–400 mg, or higher, orally once or twice daily should be given for disease in the chest, bones, and soft tissues; however, therapy must be continued for 6 months or longer after the disease is inactive to prevent relapse. In some patients with disease refractory to itraconazole or fluconazole, voriconazole or posaconazole may be beneficial. Response to therapy should be monitored by following the clinical response and progressive decrease in serum complement fixation titers.

Surgical drainage is necessary for management of soft tissue abscesses, necrotic bone and complicated pulmonary disease (eg, rupture of coccidoidal cavity).

Prognosis

The prognosis for patients with limited disease is good, but persistent pulmonary cavities may cause complications such as hemothysis or rupture producing pyopneumothorax. Nodules, cavities, and fibrotic residuals may rarely progress after long periods of stability or regression. Serial complement fixation titers should be performed after therapy for patients with coccidioidomycosis; rising titers warrant reinstitution of therapy because relapse is likely. Late central nervous system complications of adequately treated meningitis include cerebral vasculitis and hydrocephalus that may require shunting. Disseminated and meningeal forms still have mortality rates exceeding 50% in the absence of therapy.

PNEUMOCYSTOSIS (Pneumocystis jiroveci Pneumonia)

ESSENTIALS OF DIAGNOSIS

- Fever, dyspnea, nonproductive cough.
- Bilateral diffuse interstitial disease without hilar adenopathy by chest radiograph.
- Bibasilar crackles on auscultation in many cases; others have no findings.
- Reduced partial pressure of oxygen.
- P jiroveci in sputum, bronchoalveolar lavage fluid, or lung tissue.

General Considerations

Pneumocystis jiroveci, the Pneumocystis species that affects humans, is distributed worldwide. Although symptomatic P jiroveci disease is rare in the general population, serologic evidence indicates that asymptomatic infections have occurred in most persons by a young age. The overt infection is an acute interstitial plasma cell pneumonia that occurs with high frequency among two groups: (1) as epidemics of primary infections among premature or debilitated or marasmic infants on hospital wards in underdeveloped parts of the world, and (2) as sporadic cases among older children and adults who have an abnormal or altered cellular immunity. Cases occur most commonly in patients with cancer or severe malnutrition and...
debility, in patients treated with immunosuppressive or
cytotoxic drugs or irradiation for the management of
organ transplants and cancer and, most frequently, in
patients with AIDS (see Chapter 31).

The mode of transmission in primary infection is
unknown, but the evidence suggests airborne transmission.
Following asymptomatic primary infection, latent and
presumably inactive organisms are sparsely distributed in
the alveoli. Whether acute disease in older children and
adults results from de novo infection or from reactivation
of latent infection is not entirely clear, although both
mechanisms probably contribute.

Pneumocystis pneumonia occurs in up to 80% of AIDS
patients not receiving prophylaxis and is a major cause of
death. Its incidence increases in direct proportion to the
fall in CD4 cells, with most cases occurring at CD4 cell
counts < 200/mcL. In non-AIDS patients receiving immu-
nosuppressive therapy, symptoms frequently begin after
corticosteroids have been tapered or discontinued.

Clinical Findings

A. Symptoms and Signs

Findings are usually limited to the pulmonary paren-
chyma; extrapulmonary disease is reported rarely. In the
sporadic form of the disease associated with deficient cell-
mediated immunity, the onset is typically abrupt, with
fever, tachypnea, shortness of breath, and usually nonpro-
ductive cough. Pulmonary physical findings may be slight
and disproportionate to the degree of illness and the
radiologic findings; many patients have bibasilar crackles,
but others do not. Without treatment, the course is usually
one of rapid deterioration and death. Adult patients may
present with spontaneous pneumothorax, usually in
patients with previous episodes or those receiving aero-
solized pentamidine prophylaxis. Patients with AIDS will
usually have other evidence of HIV-associated disease,
including fever, fatigue, and weight loss, for weeks or
months preceding the illness.

B. Laboratory Findings

Chest radiographs most often show diffuse “interstitial”
infiltration, which may be heterogeneous, miliary, or
patchy early in infection. There may also be diffuse or focal
consolidation, cystic changes, nodules, or cavitation within
nodules. Pleural effusions are not seen. About 5–10% of
patients with Pneumocystis pneumonia have normal chest
films. High-resolution chest CT scans may be quite suggest-
ve of P jiroveci pneumonia, helping distinguish it from
other causes of pneumonia.

Arterial blood gas determinations usually show hypo-
exemia with hypocapnia but may be normal; however, rapid
desaturation occurs if patients are exercised before samples
are drawn. Isolated elevation or rising levels of serum LDH
are very sensitive but not specific findings for P jiroveci.
Serologic tests are not helpful in diagnosis, but several
studies have suggested that elevated (1→3)-β-D-glucan
levels have reasonably good sensitivity and specificity
for the diagnosis of Pneumocystis pneumonia. Specific
diagnosis depends on morphologic demonstration of the
organisms in clinical specimens using specific stains. The
organism cannot be cultured. Adequate specimens can
sometimes be obtained with induced sputum by having
patients inhale an aerosol of hypertonic saline (3%) pro-
duced by an ultrasonic nebulizer. Specimens are then
stained with Giemsa stain or methenamine silver, either of
which allows detection of cysts. The use of monoclonal
antibody with immunofluorescence has increased the sen-
titivity of diagnosis. Alternative techniques for obtaining
specimens include bronchoalveolar lavage (sensitivity
86–97%) followed by transbronchial lung biopsy (85–97%),
if necessary. Open lung biopsy and needle lung biopsy are
infrequently done but may need to be performed to diag-
ose a granulomatous form of Pneumocystis pneumonia.

Treatment

See Table 31–5. It is appropriate to start empiric therapy for
P jiroveci pneumonia if the disease is suspected clinically;
however, in both AIDS patients and non-AIDS patients
with mild to moderately severe disease, continued treat-
ment should be based on a proved diagnosis because of
clinical overlap with other infections, the toxicity of ther-
apy, and the possible coexistence of other infectious organ-
isms. Oral trimethoprim-sulfamethoxazole (TMP-SMZ) is
the preferred agent because of its low cost and excellent
bioavailability in both AIDS patients and non-AIDS
patients with mild to moderately severe disease. Patients
suffering from nausea and vomiting or intractable diarrhea
should be given intravenous TMP-SMZ until they can tol-
erate the oral formulation. The impact of resistance of
Pneumocystis to TMP-SMZ is unclear, although increasing
rates of mutations in the DHFR gene that mediate TMP-
SMZ resistance have been reported. The best-studied
second-line option is a combination of primaquine and
clindamycin, although dapsone/trimethoprim, pentami-
dine, and atovaquone have also been used. Therapy should
be continued with the selected drug for at least 5–10 days
before considering changing agents, as fever, tachypnea,
and pulmonary infiltrates persist for 4–6 days after starting
treatment. Some patients have a transient worsening of
their disease during the first 3–5 days, which may be related
to an inflammatory response secondary to the presence
of dead or dying organisms. Early addition of corticoste-
roids may attenuate this response (see Chapter 31). Some
clinicians prefer to treat episodes of AIDS-associated
Pneumocystis pneumonia for 21 days rather than the usual
14 days recommended for non-AIDS cases.

A. Trimethoprim-Sulfamethoxazole

The dosage of TMP/SMZ is 15–20 mg/kg/d (based on
trimethoprim component) given orally or intravenously
daily in three or four divided doses for 14–21 days.
Patients with AIDS have a high frequency of hypersensiti-
tivity reactions (approaching 50%), which may include
fever, rashes (sometimes severe), malaise, neutropenia,
hepatitis, nephritis, thrombocytopenia, hyperkalemia, and
hyperbilirubinemia.
B. Primaquine/Clindamycin

Although there are strong data indicating that trimethoprim-sulfamethoxazole is optimal first-line therapy for *Pneumocystis* pneumonia, the data on alternative agents is less clear. A meta-analysis suggested that primaquine, 15–30 mg/d, plus clindamycin, 600 mg three times daily, is the best second-line therapy with superior results when compared with pentamidine. Primaquine may cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD)-deficiency.

C. Pentamidine Isethionate

The use of pentamidine has decreased as alternative agents have been studied. This drug is administered intravenously (preferred) or intramuscularly as a single dose of 3–4 mg (salt)/kg/d for 14–21 days. Pentamidine causes side effects in nearly 50% of patients. Hypoglycemia (often clinically inapparent), hyperglycemia, hyponatremia, and delayed nephrotoxicity with azotemia may occur. Rarely, a variety of other severe adverse reactions may occur, including anemia, thrombocytopenia, ventricular arrhythmias, and fatal pancreatitis. Blood glucose levels should be monitored. Inadvertent rapid intravenous infusion may cause precipitous hypotension.

D. Atovaquone

Atovaquone is approved by the US Food and Drug Administration (FDA) for patients with mild to moderate disease who cannot tolerate TMP-SMZ or pentamidine, but failure is reported in 15–30% of cases. Mild side effects are common, but no serious reactions have been reported. The dosage is 750 mg three times daily for 21 days. Atovaquone should be administered with a fatty meal.

E. Other Drugs

Trimethoprim, 15 mg/kg/d in three divided doses daily, plus dapsone, 100 mg/d, is an alternative oral regimen for mild to moderate disease or for continuation of therapy after intravenous therapy is no longer needed.

F. Prednisone

Based on studies done in patients with AIDS, prednisone is given for moderate to severe pneumonia (when PaO₂ on admission is < 70 mm Hg or oxygen saturation is < 90%) in conjunction with antimicrobials. The dosage of prednisone is 40 mg twice daily orally for 5 days, then 40 mg daily for 5 days, and then 20 mg daily until therapy is completed. The role of prednisone in non-AIDS patients is unclear, especially in patients in whom symptoms developed following tapering doses of corticosteroids.

G. Supportive Care

Oxygen therapy is indicated to maintain the oxygen saturation over 90% by pulse oximetry.

Prevention

Primary prophylaxis for *Pneumocystis* pneumonia in HIV-infected patients should be given to persons with CD4 counts < 200 cells/mcL, a CD4 percentage below 14%, or weight loss or oral candidiasis (see Table 31–4). Primary prophylaxis is often used in patients with hemoglobin malignancy and transplant recipients, although the clinical characteristics of persons with these conditions who would benefit from *Pneumocystis* prophylaxis have not been clearly defined. Patients with a history of *Pneumocystis* pneumonia should receive secondary prophylaxis until they have had a durable virologic response to antiretroviral therapy for at least 3–6 months and maintain a CD4 count of > 200 cells/mcL.

Prognosis

In the absence of early and adequate treatment, the fatality rate for the endemic infantile form of *Pneumocystis* pneumonia is 20–50%; for the sporadic form in immunodeficient persons, the fatality rate is nearly 100%. Early treatment reduces the mortality rate to about 3% in the former and 10–20% in AIDS patients. The mortality rate in other immunodeficient patients is still 30–50%, probably because of failure to make a timely diagnosis. In immunodeficient patients who do not receive prophylaxis, recurrences are common (30% in AIDS).

**General Considerations**

Cryptococcosis is mainly caused by *Cryptococcus neoformans*, an encapsulated budding yeast that has been found worldwide in soil and on dried pigeon dung. *C gattii* is a closely related species that also causes disease in humans although *C gattii* may affect more immunocompetent persons. It has been emerging as a major cause of cryptococcosis in the Pacific Northwestern region of the United States and may result in more severe disease than *C neoformans*.

Infections are acquired by inhalation. In the lung, the infection may remain localized, heal, or disseminate. Clinically apparent cryptococcal pneumonia rarely develops in immunocompetent persons, except in those individuals infected by *C gattii*. Progressive lung disease and dissemination most often occur in the setting of cellular immunodeficiency, including underlying hematologic cancer under treatment, Hodgkin disease, long-term corticosteroid therapy, solid-organ transplant, TNF-inhibitor therapy, or HIV infection.

**Clinical Findings**

**A. Symptoms and Signs**

Pulmonary disease ranges from simple nodules to widespread infiltrates leading to respiratory failure. Disseminated disease may involve any organ, but central nervous system disease predominates. Headache is usually the first symptom of meningitis. Confusion and other mental status changes as well as cranial nerve abnormalities, nausea, and vomiting may be seen as the disease progresses. Nuchal rigidity and meningeal signs occur about 50% of the time but are uncommon in HIV-infected patients. Communicating hydrocephalus may complicate the course. *C gattii* infection frequently presents with neurologic signs caused by space-occupying lesions. Primary *C neoformans* infection of the skin may mimic bacterial cellulitis, especially in immunocompromised persons. Clinical worsening associated with improved immunologic status has been reported in HIV-positive and transplant patients with cryptococcosis; this entity has been labeled the immune reconstitution inflammatory syndrome (IRIS).

**B. Laboratory Findings**

Respiratory tract disease is diagnosed by culture of respiratory secretions or pleural fluid. For suspected meningeal disease, lumbar puncture is the preferred diagnostic procedure. Spinal fluid findings include increased opening pressure, variable pleocytosis, increased protein, and decreased glucose, though as many as 50% of AIDS patients have no pleocytosis. Gram stain of the cerebrospinal fluid usually reveals budding, encapsulated fungal cells. Cryptococcal capsular antigen in cerebrospinal fluid and culture together establish the diagnosis over 90% of the time. Patients with AIDS often have the antigen in both cerebrospinal fluid and serum, and extrameningeal disease (lungs, blood, urinary tract) is common. In patients with AIDS, the serum cryptococcal antigen is also a sensitive screening test for meningitis, being positive in over 95% of cases. MRI is more sensitive than CT in finding central nervous system abnormalities such as cryptococcomas.

**Treatment**

Because of decreased efficacy, initial therapy with an azole alone is not recommended for treatment of acute cryptococcal meningitis. Consequently, amphotericin B, 0.7–1 mg/kg/d intravenously is used for 14 days, followed by an additional 8 weeks of fluconazole, 400 mg/d orally. This regimen has been quite effective, achieving clinical responses and cerebrospinal fluid sterilization in about 70% of patients. Lipid amphotericin B preparations (eg, liposomal amphotericin B, 3–4 mg/kg/d) have equivalent efficacy to conventional amphotericin B with reduced nephrotoxicity. The addition of flucytosine has been associated with improved survival, but toxicity is common. Flucytosine is administered orally at a dose of 100 mg/kg/d divided into four equal doses and given every 6 hours. Hematologic parameters should be closely monitored during flucytosine therapy, and it is important to adjust the dose for any decreases in renal function. Fluconazole (800–1200 mg orally daily) may be given with amphotericin B when flucytosine is not available or patients cannot tolerate it. Frequent, repeated lumbar punctures or ventricular shunting should be performed to relieve high cerebrospinal fluid pressures or if hydrocephalus is a complication. Failure to adequately relieve raised intracranial pressure is a major cause of morbidity and mortality. The end points for amphotericin B therapy and for switching to oral fluconazole are a favorable clinical response (decrease in temperature; improvement in headache, nausea, vomiting, and mini-mental status scores), improvement in cerebrospinal fluid biochemical parameters and, most importantly, conversion of cerebrospinal fluid culture to negative.

A similar approach is reasonable for patients with cryptococcal meningitis in the absence of AIDS, though the mortality rate is considerably higher. Therapy is generally continued until cerebrospinal fluid cultures become negative. Maintenance antifungal therapy is important after treatment of an acute episode in HIV-related cases, since otherwise the rate of relapse is > 50%. Fluconazole, 200 mg/d orally, is the maintenance therapy of choice, decreasing the relapse rate approximately tenfold compared with placebo and threefold compared with weekly amphotericin B in patients whose cerebrospinal fluid has been sterilized by the induction therapy. After successful therapy of cryptococcal meningitis, it is possible to discontinue secondary prophylaxis with fluconazole in individuals with AIDS who have had a satisfactory response to antiretroviral therapy (eg, CD4 cell count > 100–200 cells/μl for at least 6 months). Among practitioners treating patients without AIDS, there has been a trend in recent years to prescribe a course (eg, 6–12 months) of fluconazole as maintenance therapy following successful treatment of the acute illness; recently published guidelines suggest this as an option.
Prognosis

Factors that indicate a poor prognosis include the activity of the predisposing conditions, older age, organ failure, lack of spinal fluid pleocytosis, high initial antigen titer in either serum or cerebrospinal fluid, decreased mental status, increased intracranial pressure, and the presence of disease outside the nervous system.

ASPERGILLOSIS

ESSENTIALS OF DIAGNOSIS

- Most common cause of non-candidal invasive fungal infection in stem cell or organ transplant patients.
- Predisposing factors: leukemia, bone marrow or organ transplant, late HIV infection.
- Pulmonary, sinus, and CNS are most common disease sites.
- Demonstration of galactomannan or β-D-glucan in serum or other body fluid samples is useful for early diagnosis and treatment.

General Considerations

Aspergillus fumigatus is the usual cause of aspergillosis, though many species of Aspergillus may cause a wide spectrum of disease. The lungs, sinuses, and brain are the organs most often involved. Clinical illness results either from an aberrant immunologic response or tissue invasion.

Clinical Findings

A. Allergic Bronchopulmonary Aspergillosis

This form of aspergillosis occurs in patients with preexisting asthma who develop worsening bronchospasm and fleeting pulmonary infiltrates accompanied by eosinophilia, high levels of IgE, and IgG Aspergillus precipitins in the blood. It also may complicate cystic fibrosis.

B. Invasive Aspergillosis

Invasive manifestations may be seen in immunocompetent or only mildly immunocompromised adults. These include chronic sinusitis, colonization of preexisting pulmonary cavities (aspergilloma), and chronic necrotizing pulmonary aspergillosis.

1. Sinusitis—Sinus involvement is usually diagnosed histologically after patients with chronic sinus disease undergo surgery.

2. Aspergillomas—Aspergillomas of the lung occur when preexisting lung cavities become secondarily colonized with Aspergillus species. These may be found by incidental radiographic studies but may also present with significant hemoptysis.

3. Chronic necrotizing aspergillosis—This invasive manifestation is a relatively rare disease seen in patients with some degree of immunocompromise and presents with a protracted course compared with the more common acute invasive form of the disease. Fibrosis and cavity formation may be prominent.

4. Life-threatening invasive aspergillosis—Severe invasive aspergillosis most commonly occurs in profoundly immunodeficient patients, particularly in patients who have undergone hematopoietic stem cell transplants; in those with prolonged, severe neutropenia; and in patients with chronic granulomatous disease. Specific risk factors in patients who have undergone a hematopoietic stem cell transplant include cytopenias, corticosteroid use, iron overload, cytomegalovirus disease, and graft-versus-host disease. Pulmonary disease is most common, with patchy infiltration leading to a severe necrotizing pneumonia. Invasive sinus disease also occurs. There is often tissue infarction as the organism grows into blood vessels; clues to this are the development of pleuritic chest pain and elevation of serum LDH. At any time, there may be hematogenous dissemination to the central nervous system, skin, and other organs. Early diagnosis and reversal of any correctable immunosuppression are essential. Blood cultures have very low yield. Detection of galactomannan by ELISA or β-D-glucan, or both, has been used for the early diagnosis of invasive disease, though multiple determinations should be done. Higher galactomannan levels are correlated with increased mortality. False-positive galactomannan tests have been reported in patients receiving β-lactam antibiotics. Isolation of Aspergillus from pulmonary secretions does not necessarily imply invasive disease, although its positive predictive value increases with more advanced immunosuppression. Therefore, a definitive diagnosis requires demonstration of Aspergillus in tissue or culture from a sterile site. CT scan of the chest may show characteristics quite suggestive of invasive aspergillosis (eg, “halo sign”).

Prevention

The high mortality rate and difficulty in diagnosis of invasive aspergillosis often leads clinicians to institute prophylactic therapy for patients with profound immunosuppression. The best-studied agents include fluconazole, itraconazole, voriconazole, and posaconazole, although patient and agent selection criteria remain undefined. Widespread use of broad-spectrum azoles raises concern for development of invasive disease by highly resistant fungi.
Treatment

A. Allergic Bronchopulmonary Aspergillosis

For acute exacerbations, oral prednisone is begun at a dose of 1 mg/kg/d and then tapered slowly over several months. Itraconazole at a dose of 200 mg daily for 16 weeks appears to improve pulmonary function and decrease corticosteroid requirements in these patients, although voriconazole may become the preferred oral agent. Some patients treated with the anti-IgE monoclonal antibody omalizumab have shown improvement in respiratory symptoms and lung function.

B. Invasive Aspergillosis

1. Sinusitis—These patients may require protracted courses of antifungals (itraconazole, 200 mg twice daily, for weeks to months) in addition to the surgical debridement.

2. Aspergilloma—The most effective therapy for symptomatic aspergilloma remains surgical resection.

3. Chronic necrotizing aspergillosis—Guidelines suggest some benefits from prolonged oral voriconazole (200 mg twice daily) or itraconazole (200 mg twice daily) therapy.

4. Life-threatening invasive aspergillosis—When severe invasive aspergillosis is considered clinically likely or is demonstrable by laboratory testing, rapid institution of voriconazole, high doses of liposomal amphotericin B (3–5 mg/kg/d), or caspofungin may be life-saving. Voriconazole (6 mg/kg intravenously twice on day 1, then 4 mg/kg/d thereafter) has been shown to be more effective, improve survival, and be associated with fewer severe side effects than conventional amphotericin B when used as initial therapy in invasive aspergillosis. Oral dosing of voriconazole at 4 mg/kg twice daily can be used for less serious infections or as a step-down strategy after intravenous therapy.

Caspofungin (70 mg intravenously on day 1, then 50 mg/d thereafter) is approved for the treatment of invasive aspergillosis in patients who do not respond to or are intolerant of other treatments. Other options include mica- fungin (100–150 mg/d intravenously) and posaconazole (200 mg orally four times daily). In critically ill patients who are not responding to conventional antifungal treatment, there may be a role for the addition of caspofungin to liposomal amphotericin B or voriconazole therapy, although randomized trials are lacking. Surgical debridement is generally done for sinusitis, and there is increasing data regarding resection of focal pulmonary lesions, especially for treatment of life-threatening hemoptysis. The mortality rate of pulmonary or disseminated disease in the immunocompromised patient remains well above 50%, particularly in patients with refractory neutropenia.

MUCORMYCOSIS

The term “mucormycosis” (zygomycosis, phycomycosis) is applied to opportunistic infections caused by members of the genera Rhizopus, Mucor, Absidia, and Cunninghamella. Predisposing conditions include hematologic malignancy, stem cell transplantation, solid organ transplantation, diabetic ketoacidosis, chronic kidney disease, desferoxamine therapy, and treatment with corticosteroids or cytotoxic drugs. These organisms appear in tissues as broad, branching nonseptate hyphae. Biopsy with histologic examination is almost always required for diagnosis; cultures are frequently negative. Invasive disease of the sinuses, orbits, and the lungs may occur. Widely disseminated disease is seen in patients who have received aggressive chemotherapy and broad-spectrum antifungal prophylaxis. A prolonged course of a lipid preparation of amphotericin B should be started early. Based on in vitro susceptibility and reports of successful salvage therapy, there may be a role for posaconazole in the treatment of these infections following control of acute infection by amphotericin. Other azoles are not effective. There are limited data suggesting beneficial synergistic activity when amphotericin and caspofungin are used in combination for mucormycosis. Despite favorable animal studies, a recent pilot study in humans incorporating adjunctive iron chelation therapy with deferasirox demonstrated a higher mortality rate than antifungal therapy alone. Control of diabetes and other underlying conditions, along with extensive repeated surgical removal of necrotic, nonperfused tissue, is essential. Even when these measures are introduced in a timely fashion, the prognosis is poor, with a 30–50% mortality rate for localized disease and higher rates in disseminated cases.

BLASTOMYCOSIS

Blastomycosis occurs most often in men infected during occupational or recreational activities out of doors in a geographically limited area of the south central and midwestern United States and Canada. Disease usually occurs in immunocompetent individuals.

Chronic pulmonary infection is most common and may be asymptomatic. When dissemination takes place, lesions are most frequently seen in the skin, bones, and urogenital system.

Cough, moderate fever, dyspnea, and chest pain are common. These may resolve or progress, with purulent sputum production, pleurisy, fever, chills, loss of weight, and prostration. Radiologic studies, either chest radiographs or CT scans, usually reveal airspace consolidation or masses.
Raised, verrucous cutaneous lesions are commonly present in disseminated blastomycosis. Bones—often the ribs and vertebrae—are frequently involved. Epididymitis, prostatitis, and other involvement of the male urogenital system may occur. Although they do not appear to be at greater risk for acquisition of disease, infection in HIV-infected persons may progress rapidly, with dissemination common.

Laboratory findings usually include leukocytosis and anemia, though these are not specific. The organism is found in clinical specimens, such as expectorated sputum or tissue biopsies, as a thick-walled cell 5–20 mcm in diameter that may have a single broad-based bud. It grows readily on culture. Serologic tests are not well standardized. A urinary antigen test is available, but it has considerable cross-reactivity with Histoplasma; consequently, its usefulness in diagnosis and in assessing response to therapy is unclear.

Itraconazole, 200–400 mg/d orally for at least 2–3 months, is the therapy of choice for nonmeningeal disease, with a response rate of over 80%. Amphotericin B, 0.7–1.0 mg/kg/d intravenously (or lipid formulation amphotericin B), is given for severe disease, treatment failures, or central nervous system involvement.

Clinical follow-up for relapse should be made regularly for several years so that therapy may be resumed or another drug instituted.

Laboratory findings are nonspecific. Serology by immunodiffusion is positive in 98% of cases. Complement fixation titers correlate with progressive disease and fall with effective therapy. The fungus is found in clinical specimens as a spherical cell that may have many buds arising from it. If direct examination of secretions does not reveal the organism, biopsy with Gomori staining may be helpful.

Itraconazole, 100 mg twice daily orally, is the treatment of choice and generally results in a clinical response within 1 month and effective control after 2–6 months. Voriconazole, 200 mg twice daily orally, appears to be as effective as itraconazole. Amphotericin B intravenously is the drug of choice for severe and life-threatening infection.

Sporotrichosis is a chronic fungal infection caused by Sporothrix schenckii. It is worldwide in distribution; most patients have had contact with soil, sphagnum moss, or decaying wood. Transmission from animals to humans has also been reported. Infection takes place when the organism is inoculated into the skin—usually on the hand, arm, or foot, especially during gardening.

The most common form of sporotrichosis begins with a hard, nontender subcutaneous nodule. This later becomes adherent to the overlying skin and ulcerates. Within a few days to weeks, similar nodules develop along the lymphatics draining this area, and these may ulcerate as well.

Disseminated sporotrichosis is rare in the immunocompetent person but may present with widespread cutaneous, lung, bone, joint, and central nervous system involvement in immunocompromised patients, especially those with AIDS and alcohol abuse.

Cultures are needed to establish diagnosis. Antibody tests may be useful for diagnosis of disseminated disease, especially meningitis.

Itraconazole, 200–400 mg orally daily for several months, is the treatment of choice for localized disease and some milder cases of disseminated disease. Terbinafine, 500 mg orally twice daily, also appears to have good efficacy in lymphocutaneous disease. Amphotericin B intravenously, 1–2 g, is used for severe systemic infection. Surgery is usually contraindicated except for simple aspiration of secondary nodules. Joint involvement may require arthrodesis.

The prognosis is good for lymphocutaneous sporotrichosis; pulmonary, joint, and disseminated disease respond less favorably.

**PARACOCCIDIOIDOMYCOSIS (South American Blastomycosis)**

Paracoccidioides brasiliensis infections have been found only in patients who have resided in South or Central America or Mexico. Long asymptomatic periods enable patients to travel far from the endemic areas before developing clinical problems. Weight loss, pulmonary complaints, or mucosal ulcerations are the most common symptoms. Cutaneous papules may ulcerate and enlarge both peripherally and deeper into the subcutaneous tissue. Differential diagnosis includes mucocutaneous leishmaniasis and syphilis. Extensive coalescent ulcerations may eventually result in destruction of the epiglottis, vocal cords, and uvula. Extension to the lips and face may occur. Eating and drinking are extremely painful. Skin lesions may occur, usually on the face. Variable in appearance, they may have a necrotic central crater with a hard hyperkeratotic border. Lymph node enlargement may follow mucocutaneous lesions, eventually ulcerating and forming draining sinuses; in some patients, it is the presenting symptom. Hepatosplenomegaly may be present as well. HIV-infected patients with paracoccidioidomycosis are more likely to have extra-pulmonary dissemination and a more rapid clinical disease course.

Paracoccidioides provides a capsule-like structure that presents with granulomatous inflammation. Infection may be disseminated, i.e., hematogenous, owing to the formation of 5–20 mcm capsules with a single broad-based bud. It is found in clinical specimens, such as expectorated sputum or tissue biopsies, as a thick-walled cell 5–20 mcm in diameter that may have a single broad-based bud. It grows readily on culture. Serologic tests are not well standardized. A urinary antigen test is available, but it has considerable cross-reactivity with Histoplasma; consequently, its usefulness in diagnosis and in assessing response to therapy is unclear.

Itraconazole, 200–400 mg/d orally for at least 2–3 months, is the therapy of choice for nonmeningeal disease, with a response rate of over 80%. Amphotericin B, 0.7–1.0 mg/kg/d intravenously (or lipid formulation amphotericin B), is given for severe disease, treatment failures, or central nervous system involvement.

Clinical follow-up for relapse should be made regularly for several years so that therapy may be resumed or another drug instituted.

Laboratory findings are nonspecific. Serology by immunodiffusion is positive in 98% of cases. Complement fixation titers correlate with progressive disease and fall with effective therapy. The fungus is found in clinical specimens as a spherical cell that may have many buds arising from it. If direct examination of secretions does not reveal the organism, biopsy with Gomori staining may be helpful.

Itraconazole, 100 mg twice daily orally, is the treatment of choice and generally results in a clinical response within 1 month and effective control after 2–6 months. Voriconazole, 200 mg twice daily orally, appears to be as effective as itraconazole. Amphotericin B intravenously is the drug of choice for severe and life-threatening infection.

Sporotrichosis is a chronic fungal infection caused by Sporothrix schenckii. It is worldwide in distribution; most patients have had contact with soil, sphagnum moss, or decaying wood. Transmission from animals to humans has also been reported. Infection takes place when the organism is inoculated into the skin—usually on the hand, arm, or foot, especially during gardening.

The most common form of sporotrichosis begins with a hard, nontender subcutaneous nodule. This later becomes adherent to the overlying skin and ulcerates. Within a few days to weeks, similar nodules develop along the lymphatics draining this area, and these may ulcerate as well.

Disseminated sporotrichosis is rare in the immunocompetent person but may present with widespread cutaneous, lung, bone, joint, and central nervous system involvement in immunocompromised patients, especially those with AIDS and alcohol abuse.

Cultures are needed to establish diagnosis. Antibody tests may be useful for diagnosis of disseminated disease, especially meningitis.

Itraconazole, 200–400 mg orally daily for several months, is the treatment of choice for localized disease and some milder cases of disseminated disease. Terbinafine, 500 mg orally twice daily, also appears to have good efficacy in lymphocutaneous disease. Amphotericin B intravenously, 1–2 g, is used for severe systemic infection. Surgery is usually contraindicated except for simple aspiration of secondary nodules. Joint involvement may require arthrodesis.

The prognosis is good for lymphocutaneous sporotrichosis; pulmonary, joint, and disseminated disease respond less favorably.
**CHROMOBLASTOMYCOSIS (Chromomycosis)**

Chromoblastomycosis is a chronic, principally tropical cutaneous infection usually affecting young men who are agricultural workers and caused by several species of closely related black molds; *Cladophialophora carrionii* and *Fonsecaea pedrosi* are the most common etiologic agents.

Lesions usually follow puncture wounds and are slowly progressive, occurring most frequently on a lower extremity. The lesion begins as a papule or ulcer. Over months to years, papules enlarge to become vegetating, papillomatous, verrucous elevated nodules. Satellite lesions may appear along the lymphatics. There may be secondary bacterial infection. Elephantiasis may result.

The fungus is seen as brown, thick-walled, spherical, sometimes septate cells in potassium hydroxide preparations of pus or skin scrapings, which are quite sensitive for diagnosis. The type of reproduction found in culture determines the species.

Itraconazole, 200–400 mg/d orally for 6–18 months, achieves a response rate of 65%. Terbinafine at 500–1000 mg/d orally may have similar efficacy to itraconazole and may be useful in combination, especially in difficult to treat cases. Cryosurgery alone for smaller lesions or combined with itraconazole for larger lesions is beneficial.

**MYCETOMA (Maduromycosis & Actinomycetoma)**

Mycetoma is a chronic, local, slowly progressive destructive infection, usually involving the foot, that begins in subcutaneous tissues, frequently after localized trauma, and then spreads to contiguous structures. Maduromycosis (also known as eumycetoma) is the term used to describe mycetoma caused by the true fungi and by phylogenetically diverse organisms. Actinomycotic mycetoma is caused by *Nocardia* and *Actinomadura* species. The disease begins as a papule, nodule, or abscess that over months to years progresses slowly to form multiple abscesses and sinus tracts ramifying deep into the tissue. Secondary bacterial infection may result in large open ulcers. Radiographs may show destructive changes in the underlying bone. Tissue Gram stain reveals fine branching hyphae with actinomycotic mycetoma. Larger hyphae are seen with fungal mycetoma; the causative species can often be identified by the color of the characteristic grains within the infected tissues.

The prognosis is good for patients with actinomycetoma, since they usually respond well to sulfonamides and sulfones, especially if treated early. TMP-SMZ, 160/800 mg orally twice a day, or dapson, 100 mg twice daily after meals, has been reported to be effective. Streptomycin, 14 mg/kg/d intramuscularly, may be useful during the first month of therapy. All oral medications must be taken for months and continued for several months after clinical cure to prevent relapse. Debridement assists healing.

The prognosis for maduromycosis is poor, though surgical debridement along with prolonged itraconazole therapy may result in a response rate of 70%. The various etiologic agents may respond differently to antifungal agents, so culture results are invaluable. Amputation is necessary in far advanced cases.

**OTHER OPPORTUNISTIC MOLD INFECTIONS**

Fungi previously considered to be harmless colonizers, including *Pseudallescheria boydii* (*Scedosporium apiospermum*), *Scedosporium prolificans*, *Fusarium*, *Paecilomyces*, *Trichoderma longibrachiatum*, and *Trichosporon*, are emerging as significant pathogens in immunocompromised patients. This occurs most often in patients being treated for hematopoietic malignancies and in those receiving broad-spectrum antifungal prophylaxis. Infection may be localized in the skin, lungs, or sinuses, or widespread disease may appear with lesions in multiple organs. Fusariosis should be suspected in severely immunosuppressed persons in whom multiple, painful skin lesions develop; blood cultures are often positive. Sinus infection may cause bony erosion. Infection in subcutaneous tissues following traumatic implantation may develop as a well-circumscribed cyst or as an ulcer.

Nonpigmented septate hyphae are seen in tissue and are indistinguishable from those of *Aspergillus* when infections...
are due to *S. apiospermum* or species of *Fusarium*, *Paecilomyces*, *Penicillium*, or other hyaline molds. Spores or mycetoma-like granules are rarely present in tissue. The differentiation of *S. apiospermum* and *Aspergillus* is particularly important, since the former is uniformly resistant to amphotericin B but may be sensitive to azole antifungals (eg, voriconazole). Infection by any of a number of black molds is designated as phaeohyphomycosis. These black molds (eg, *Exophiala, Bipolaris, Cladophialophora, Curvularia, Alternaria*) are common in the environment, especially on decaying vegetation. Human disease due to these agents is rarely encountered but may result in soft tissue abscesses due to traumatic inoculation or may occur as a sequela of chronic sinusitis or profound immunosuppression. In tissues of patients with phaeohyphomycosis, the mold is seen as black or faintly brown hyphae, yeast cells, or both. Culture on appropriate medium is needed to identify the agent. Histologic demonstration of these organisms is definitive evidence of invasive infection; positive cultures must be interpreted cautiously and not assumed to be contaminants in immunocompromised hosts. Some isolates are sensitive to antifungal agents.

---

1 No dosage adjustment required for chronic kidney disease; dosage adjustment necessary with moderate to severe hepatic dysfunction.

2 Use should be monitored with blood levels to prevent this or the dose adjusted according to creatinine clearance.

3 In combination with amphotericin B.

4 Administration with drugs that are metabolized by the cytochrome P450 system is contraindicated or requires careful monitoring.

5 Some authorities advocate therapeutic drug monitoring in patients who are not responding to therapy.

---

cryptococcal meningitis. Their principal advantage appears to be substantially reduced nephrotoxicity, allowing administration of much higher doses. Three agents of the echinocandin class, caspofungin acetate, anidulafungin, and micafungin sodium, are currently approved. The echinocandins have relatively few adverse effects and are useful for the treatment of invasive Candida infections. Caspofungin acetate is also approved for use in refractory cases of invasive aspergillosis. Voriconazole has excellent activity against a broad range of fungal pathogens and has been FDA approved for use in invasive Aspergillus cases, Fusarium and Scedosporium infections, Candida esophagitis, deep Candida infections, and candidemia. Posaconazole has good activity against a broad range of filamentous fungi, including the zygomycetes. Some experts now recommend therapeutic drug monitoring in individuals with severe invasive fungal infections receiving these newer azoles because of unreliable serum levels due to either metabolic alterations as a result of genetic polymorphisms (voriconazole) or erratic absorption (posaconazole). As a result of their more frequent and sometimes extended use, newly recognized adverse drug effects are being recognized with the azoles, including peripheral neuropathy (itraconazole and voriconazole) and fluoride excess resulting in periostitis and alkaline phosphatase elevations (voriconazole).

---

The human body maintains a steady temperature through the balance of internal heat production and environmental heat loss. Heat exchange between the body and environment occurs via four common processes: radiation, evaporation, conduction, and convection. In extreme temperatures, the body’s thermoregulation may fail. This results in the body’s internal temperature moving toward the temperature of the external environment.

Temperature-related conditions may arise in any individual, regardless of sex, race, age, or underlying health status. Cold and heat exposure may cause a wide spectrum of conditions; the severity varies considerably among individuals. The likelihood and severity of extreme temperature-related conditions depend on physiologic and environmental factors. Physiologic risk factors include underlying medical conditions (cardiopulmonary, vascular, neurologic, psychiatric, musculoskeletal, immunologic, hematologic, endocrine [hypothyroidism, adrenal insufficiency, hypopituitarism], renal, hepatic, and infectious diseases); extremes of age; cognitive impairment; poor physical conditioning/sedentary lifestyle; poor acclimatization; concurrent injury; inadequate thermoregulation; prior temperature-related injury; and pharmacologic effects (ie, medications, recreational drugs, tobacco, and alcohol). Environmental risk factors include inadequate clothing, inadequate housing, occupational or recreational exposure.

## ACCIDENTAL SYSTEMIC HYPOTHERMIA

**Essentials of Diagnosis**

- Hypothermia is a reduction of core body temperature below 35°C.
- To accurately measure hypothermia, an intravascular, esophageal, rectal, or bladder probe that measures temperatures as low as 25°C is required; oral, axillary, and otic temperatures are inaccurate and unreliable.

**General Considerations**

Systemic hypothermia is defined as core body temperature < 35°C. This may be primary (from exposure to prolonged ambient extremely low temperature) or secondary (due to thermoregulatory dysfunction). Primary and secondary hypothermia may also be present at the same time. Hypothermia risk factors include prior cold weather injury as well as those factors listed in the Cold & Heat section. Heat loss occurs more rapidly with high wind velocity (“windchill factor”), water exposure (including wet clothing), or direct contact with a cold surface.

The human body generates internal heat through muscle activity (ie, shivering or increased physical exertion) and preserves heat loss via peripheral vasoconstriction. In prolonged or repetitive cold exposure, these thermoregulatory responses can become impaired; hypothermia ensues. Hypothermia diagnosis can be easily overlooked and delayed in a critically ill or injured patient. Hypothermia should be considered in any patient with prolonged exposure to ambient or cold environment, trauma, inadequate clothing, or altered mental status.

Systemic hypothermia depresses physiologic function, resulting in decreased respiratory drive, oxygen consumption, central and peripheral nerve conduction, gastrointestinal motility, myocardial repolarization, and coagulation cascade. Accidental hypothermia may occur iatrogenically in the hospital setting. This section does not cover induced hypothermia post-resuscitation by critical care specialists.

**Clinical Findings**

Symptoms and signs of hypothermia are typically non-specific and markedly variable based on the patient’s...
underlying health and circumstances of hypothermia. At body core temperatures between 32°C and 35°C, symptoms include tachypnea, tachycardia, hypertension, shivering, impaired coordination, poor judgment, and apathy. At body core temperature between 32°C and 28°C, the body slows down. Shivering stops; bradycardia, dilated pupils, slowed reflexes, cold diuresis, and confusion and lethargy ensue. The electrocardiogram (ECG) may reveal a J wave or Osborn wave (positive deflection in the terminal portion of the QRS complex and are best seen in the inferior and lateral precordial leads (most notably in leads II, V₅, and V₆). (Figure 37–1). In extreme hypothermia (body core temperature below 28°C), the skin may appear blue or puffy; coma, apnea, loss of reflexes, asystole, or ventricular fibrillation may lead the clinician to assume that the patient is dead. Prolonged hypothermia may lead to dysrhythmias and conduction abnormalities, acidemia, hyperkalemia, rhabdomyolysis, pulmonary edema, kidney disease, pneumonia, pancreatitis, hypoglycemia or hyperglycemia, and coagulopathy. Death from systemic hypothermia is usually due to ventricular fibrillation, asystole, or kidney disease.

Treatment

Resuscitation begins with rapid assessment and support of airway, breathing and circulation, initiation of rewarming, and prevention of further heat loss. Rewarming is the initial, imperative treatment. All cold, wet clothing must be removed and replaced with warm, dry clothing. To accurately measure hypothermia, an intravascular, esophageal, rectal or bladder probe that measures temperatures as low as 25°C is required; oral, axillary, and otic temperatures are inaccurate and unreliable. The patient should be evaluated for associated conditions of hypoglycemia, trauma, overdose and peripheral cold injury. Rewarming methods are determined by the degree of hypothermia and the resources available.

During rewarming, continuous monitoring of temperature and other vital signs, cardiac rhythm, and blood sugar must be done. Common complications of rewarming occur as colder peripheral blood returns to central circulation. This may result in core temperature afterdrop, rewarming acidosis from shunting lactate into the circulation, rewarming shock from peripheral vasodilation and hypovolemia, ventricular fibrillation and other cardiac arrhythmias. Extreme caution must be taken when handling the hypothermic patient to avoid triggering arrhythmias. During the rewarming process, essential testing includes ECG, chest radiograph, arterial blood gases, and bedside glucose. Laboratory evaluation should assess for potential complications of lactic acidosis; rhabdomyolysis; electrolyte abnormalities; infection; and dysfunction of the pancreas, liver, kidneys, and coagulation. False laboratory values will occur if the blood sample is warmed to 37°C for the testing. Antibiotics are not routinely given. Comatose patients have a high risk of aspiration pneumonia.

A. Passive and Active External Rewarming Methods

Patients with mild hypothermia (rectal temperature > 33°C) who have been otherwise healthy usually respond well to passive and active external warming. Passive external rewarming involves removal of cold wet clothing, then drying and covering the patient with blankets to prevent further heat loss. The patient will rewarm due to the body's internal heat production through shivering and increased metabolism. Active external rewarming is highly effective and safe for mild hypothermia. This is a noninvasive method of applying external heat to the patient's skin. Examples include warm bedding, heated blankets, heat packs, and immersion into a 40°C bath. Afterdrop can be lessened by active external rewarming of the trunk but not the extremities and by avoiding any muscle movement by the patient.

B. Active Internal (Core) Rewarming Methods

Active internal core rewarming methods are required for patients with core temperatures of < 33°C. Patients with milder degrees of hypothermia may also benefit from these methods. Warm humidified oxygen (43–46°C) is an easy, safe, and highly effective method. Warmed intravenous saline infusions (43°C) should be used instead of lactated Ringer solution. Volume resuscitation is needed to prevent shock as vasodilation occurs during rewarming. Other rewarming methods are based on the availability of equipment and skilled personnel (ie, warm solution lavage; esophageal rewarming tubes; endovascular warming devices; and hemodialysis).

For patients with core temperature < 30°C, initial treatment includes active rewarming, cardiopulmonary resuscitation (CPR), one shock attempt for dysrhythmia, and withholding of intravenous medications. Once the core temperature reaches 30°C, cardiac medications can be given but at intervals longer than standard intervals because metabolism is slowed and there is a risk of toxic
Hypothermia.

Otherwise healthy patients may survive moderate or severe hypothermia. If treated early, most otherwise healthy patients may survive moderate or severe hypothermia.

# Prognosis

Prognosis is directly related to the patient’s underlying health and comorbidities, circumstances surrounding the hypothermia (duration, extent, and the severity of associated conditions), and degree of metabolic acidosis. Prognosis is poor with low pH (≤ 6.6), elevated potassium (≥ 4.0 mEq/L or ≥ 4.0 mmol/L), serious underlying condition, or treatment delay. If treated early, most otherwise healthy patients may survive moderate or severe hypothermia.

# When to Admit

- Hypothermia patients must undergo close monitoring for potential complications. This is typically done during an inpatient admission or prolonged emergency department observation depending on the comorbidities and home care situation.
- Monitoring includes vital signs, temperature, cardiac rhythm, oximetry, serial examinations (including extremity cold-induced injuries), and serial laboratory studies (electrolyte abnormalities, renal or hepatic dysfunction, cardiac ischemia, and infection).

# Clinical Findings

Cold-induced injuries to the extremities (ie, frostnip, chilblain, trench foot, and frostbite) range from mild to severe. Cold exposure of the extremities produces immediate localized vasoconstriction followed by generalized vasoconstriction. When the skin temperature falls to 25°C, tissue demand for oxygen is greater than what is supplied by the slowed circulation: the area becomes cyanotic. At 15°C, tissue damage occurs due to marked reduction in tissue metabolism and oxyhemoglobin dissociation. This gives a deceptive pink, well-oxygenated appearance to the skin. Tissue damage may result from ischemia and intravascular thromboses, endothelial damage, or by actual freezing. Freezing (frostbite) may occur when the skin temperature drops below −4 to −10°C or at higher temperatures in the presence of wind, water, immobility, malnutrition, or vascular disease.

# Prevention

“Keep warm, keep dry, and keep moving.” Individuals should wear warm, dry clothing, preferably several layers, with a windproof outer garment. Arms, legs, fingers, and toes should be exercised to maintain circulation. Wet clothing, socks, and shoes should be replaced with dry ones. Extra socks, mittens, and insoles should always be carried in a pack during travel in cold or icy areas. Caution must be taken to avoid cramped positions; constrictive clothing; prolonged dependency of the feet; use of tobacco, alcohol, and sedative medications; and exposure to wet muddy ground and windy conditions.

# Frostnip & Chilblain (Erythema Pernio)

Frostnip is a mild temporary form of cold-induced injury. The involved area has local paresthesias that completely resolve with passive external rewarming. Rewarming can be done by placing cold fingers in the armpits and, in the case of the toes or heels, by removing footwear, drying feet, rewarming, and covering with adequate dry socks or other protective footwear.

Chilblains or erythema pernio are inflammatory skin changes caused by exposure to cold without actual freezing of the tissues. These skin lesions may be red or purple papular lesions, which are painful or pruritic, with burning or paresthesias. They may be associated with edema or blistering and aggravated by warmth. With continued exposure, ulcerative or hemorrhagic lesions may appear and progress to scarring, fibrosis, and atrophy. This may resemble vasculitis or peripheral thromboemboli. A detailed history of cold exposure will differentiate chilblains from these other conditions, thereby avoiding unnecessary diagnostic testing.

Treatment consists of elevating and passively externally rewarming the affected part. Caution must be taken to avoid rubbing or massaging injured tissues and to avoid applying ice or heat. The area must be protected from trauma, secondary infection, and further cold exposure.

# Immersion Foot or Trench Foot

Immersion foot (or hand) is caused by prolonged immersion in cool or cold water or mud, usually < 10°C. Prehyperemic stage is marked by early symptoms, which include cold and anesthesia of the affected area. Hyperemic stage follows with hot sensation, intense burning, and shooting pains. With ongoing cold exposure, the affected part becomes pale or cyanotic with diminished pulsations due to vasospasm (posthyperemic stage). This may result in blistering, swelling, redness, ecchymoses, hemorrhage, necrosis, peripheral nerve injury, or gangrene and secondary complications such as lymphangitis, cellulitis, and thrombophlebitis.

Treatment is best instituted during the hyperemic stage. Treatment consists of air drying, protecting the extremities from trauma and secondary infection, and...
gradual rewarming by exposure to air at room temperature (not ice or heat). Caution must be taken to avoid massaging or moistening the skin and to avoid further water immersion. Bed rest is required until all ulcers have healed. Affected parts are elevated to aid in removal of edema fluid. Pressure sites (ie, heels) are protected with pillows. Prevention involves properly fitting footwear, improved foot hygiene, and sock changes to keep feet clean and dry.

**FROSTBITE**

Frostbite is injury from tissue freezing and formation of ice crystals in the tissue. Most tissue destruction follows the reperfusion of the frozen tissues, with damaged endothelial cells and progressive microvascular thrombosis resulting in further tissue damage. In mild cases, only the skin and subcutaneous tissues are involved; the symptoms are numbness, pricking, itching, and pallor. With increasing severity, deep frostbite involves deeper structures. The skin appears white or yellow, loses its elasticity, and becomes immobile. Edema, hemorrhagic blisters, necrosis, and gangrene may appear. This may cause paresthesias and stiffness.

**Treatment**

**A. Immediate Treatment**

Evaluate and treat the patient for associated systemic hypothermia and injury. Avoid secondary exposure to cold. Early use of systemic analgesics is recommended for nonfrozen injuries. Fluids and electrolytes should be monitored.

1. **Rewarming**—Rapid rewarming at temperatures slightly above body heat may significantly decrease tissue necrosis and reverse the tissue crystallization. If there is any possibility of refreezing, the frostbitten part should not be thawed, even if this might mean prolonged walking on frozen feet. Refreezing results in increased tissue necrosis. Rewarming is best accomplished by warm bath immersion. The frozen extremity is immersed for several minutes in a moving water bath heated to 40–42°C until the distal tip of the part being thawed flushes. Dry heat (ie, stove or open fire) is more difficult to regulate, increases likelihood of accidental burns and is not recommended. Thawing may cause tenderness and burning pain. Once the frozen part has thawed and returned to normal temperature (usually in about 30 minutes), discontinue external heat. In the early stage, rewarming by exercise, rubbing, or friction is contraindicated. The patient must be kept at bed rest with the affected parts elevated and uncovered at room temperature. Casts, occlusive dressings, or bandages are not applied. Blisters should be left intact unless signs of infection supervene.

2. **Anti-infective measures and wound care**—Frostbite increases susceptibility to tetanus and infection. Tetanus prophylaxis must be considered. Infection risk may be reduced by aseptic wound care and protection of skin blebs from physical contact. Wounds should be kept open and allowed to dry before applying dressings. Nonadherent sterile gauze and fluffy dressing should be loosely applied to wounds and cushions used for all areas of pressure. Antibiotics should not be administered empirically. Systemic antibiotics are reserved for deep infections not responding to local wound care.

**B. Medical and Surgical Treatment Options**

With the availability of telemedicine, specialists are able to provide advice on early field treatment of cold-injured patients in remote areas, thereby improving outcome. Eschar formation without evidence of infection may be conservatively treated. The underlying skin may heal spontaneously with the eschar acting as a biologic dressing. Intra-arterial thrombolytic administration within 24 hours of exposure has resulted in improved tissue perfusion and has reduced amputation.

**C. Follow-Up Care**

Gentle, progressive physical therapy to promote circulation should be instituted as tolerated. Debridement and amputation should be considered only after it is established that the tissues are necrotic.

**Prognosis**

Recovery from frostbite depends on the underlying comorbidities, the extent of initial tissue damage, the rewarming reperfusion injury, and the late sequelae. The involved extremity may be at increased susceptibility for discomfort and injury upon reexposure to cold. Neuropathic sequelae such as pain, numbness, tingling, hyperhidrosis, and cold sensitivity of the extremities, and nerve conduction abnormalities may persist for many years after the cold injury.

**When to Admit**

- Patients with local cold-induced injury may require admission for management of tissue damage, comorbidities, associated injuries, or an inadequate living situation, which could compromise patient safety or recovery.

---

DISORDERS DUE TO HEAT

ESSENTIALS OF DIAGNOSIS

- There is a spectrum of preventable heat-related illnesses: heat cramps, heat exhaustion, heat syncope, and heat stroke.
- Pre-event planning and adequate preparation are the best preventive measures. Salt tablets are not recommended without medical supervision.
- The hallmarks of heat stroke are hyperthermia with cerebral dysfunction in a patient with heat exposure.
- The best outcome is related to early recognition, initiation of rapid cooling, and avoidance of shivering during cooling.
- The best choice of cooling method depends on which can be instituted the fastest with the least compromise to the overall care of the patient. Delays in cooling result in higher morbidity and mortality in heat stroke victims.

General Considerations

Hyperthermia results from the body’s inability to maintain normal internal temperature through heat loss. The body’s heat source is a result of internal metabolic function and environmental conditions (temperature, humidity). Heat loss occurs through sweating and peripheral vasodilation. There is a spectrum of preventable heat-related illnesses related to environmental exposure, ranging from mild forms, such as heat cramps and heat exhaustion, to severe forms, such as heat syncope and heat stroke. The common comorbidities and risk factors leading to heat-related conditions are listed in the chapter’s introduction “Cold & Heat” section. Additional risk factors include duration of exertion, hot environment, physical inactivity, and insufficient acclimatization, skin disorders or other medical conditions that inhibit sweat production or evaporation, obesity, dehydration, prolonged seizures, hypotension, reduced cutaneous blood flow, reduced cardiac output, the use of drugs that increase metabolism or muscle activity or impair sweating, and withdrawal syndromes. Nonexertional heat-related illness can also occur in a hot relaxing environment (ie, hot bath, steam room, or sauna).

Prevention

Public education is necessary to improve prevention and early recognition of heat-related disorders. Individuals should take steps to reduce personal risk factors and to acclimatize to the hot environment. Acclimatization is achieved by scheduled regulated exposure to hot environments and by gradually increasing the duration of exposure and the workload until the body adjusts. Proper acclimatization must be achieved before heavy physical exertion is performed in hot environments. Heat-related illnesses are the leading cause of morbidity and mortality in high school sports in the United States. All children’s athletic programs must set heat-acclimatization guidelines. Parents, coaches, athletic trainers and athletes must be educated about heat-related illness, specifically about prevention, risks, signs and symptoms, and treatment.

Medical evaluation and monitoring should be used to identify the individuals and the weather conditions that increase risk of heat-related disorders. Athletic events should be organized with attention to thermoregulation. Guidance regarding heat hazard is found in the National Weather Service’s Heat Index, which rates weather conditions based on humidity and temperature measurements (http://www.nws.noaa.gov/os/heat/index.shtml).

Those who are physically active in a hot environment should increase fluid consumption before, during, and after physical activities. Fluid consumption should include balanced electrolyte fluids and water. Water consumption alone may lead to electrolyte imbalance, particularly hyponatremia. It is not recommended to have salt tablets available for use without medical supervision. Close monitoring of fluid and electrolyte intake and early intervention are recommended in situations necessitating exertion or activity in hot environments. Exertional heat-related disorders are common in unconditioned participants in strenuous activities in hot humid conditions. Classic (non-exertional) heat-related disorders occur when extreme environmental conditions (heat, humidity) affect patients who are not physically active, in the extremes of ages, or with chronic medical or psychiatric illnesses.

SPECIFIC SYNDROMES DUE TO HEAT EXPOSURE

1. Heat Syncope or Collapse

Heat syncope or sudden collapse may result in unconsciousness from volume depletion and cutaneous vasoconstriction with consequent systemic and cerebral hypotension. Exercise-associated postural hypotension is usually the cause of this: it may occur during or immediately following exercise. There is usually a history of prolonged vigorous physical activity or prolonged standing in a hot humid environment. Typically, the skin is cool and moist, the pulse is weak, and the systolic blood pressure is low.

Treatment consists of rest and recumbency in a cool place and fluid and electrolyte rehydration by mouth (or intravenously if necessary).

2. Heat Cramps

Fluid and electrolyte depletion may result in slow, painful skeletal muscle contractions (“cramps”) and severe muscle spasms lasting 1–3 minutes, usually of the muscles most heavily used. The skin is moist and cool. The muscles are tender, hard and lumpy, and muscle twitching may be present. The patient is alert, with stable vital signs, and may be agitated and complaining of focal pain. The body temperature may be normal or slightly increased. There is almost always a history of vigorous activity just preceding the onset of symptoms.
The patient should be moved to a cool environment and given oral saline solution (4 tsp of salt per gallon of water) to replace both salt and water. Oral salt tablets are not recommended. The patient may have to rest for 1–3 days with continued dietary supplementation before returning to work or resuming strenuous activity in the heat.

3. Heat Exhaustion

Heat exhaustion results from prolonged strenuous activity with inadequate water or salt intake in a hot environment. It is characterized by dehydration, sodium depletion, or isotonic fluid loss with accompanying cardiovascular changes.

The diagnosis is based on symptoms and clinical findings of a rectal temperature over 37.8°C, increased pulse, and moist skin. Symptoms are similar to those associated with heat syncope and heat cramps. Additional symptoms include nausea, vomiting, malaise, myalgias, hyperventilation, thirst, and weakness. Central nervous system symptoms include headache, dizziness, fatigue, anxiety, paresthesias, hysteria, impaired judgment, and occasionally psychosis. Heat exhaustion may progress to heat stroke if sweating ceases and mental status declines.

Treatment consists of moving patient to a shaded, cool environment, providing adequate hydration (1–2 L over 2–4 hours), oral salt replenishment, and active cooling (ie, fans, cool packs) if necessary. Physiologic saline or isotonic glucose solution should be administered intravenously when oral administration is not appropriate. At least 24 hours of rest and rehydration are recommended.

4. Heat Stroke

Heat stroke is a life-threatening medical emergency. The hallmarks of heat stroke are cerebral dysfunction with core temperature over 40°C. It presents in one of two forms: classic and exertional. Classic heat stroke occurs in patients with impaired thermoregulatory mechanisms; exertional heat stroke occurs in healthy persons undergoing strenuous exertion in a hot or humid environment. Persons at greatest risk are those who are at the extremes of age, chronically debilitated, and taking medications that interfere with heat-dissipating mechanisms (ie, anticholinergics, antihistamines, phenothiazines).

Heat stroke is associated with high morbidity and mortality from cerebral, cardiovascular, liver, or kidney damage. Increased mortality rates are associated with a high Simplified Acute Physiology Score II, high body temperature, prolonged prothrombin time, use of vasoactive drugs within the first day in the intensive care unit (ICU), and an ICU without air conditioning.

Clinical Findings

A. Symptoms and Signs

Heat stroke must be considered in any patient with hyperthermia and cerebral dysfunction. Presenting symptoms include all those seen in heat exhaustion with additional symptoms of dizziness, weakness, emotional lability, confusion, delirium, blurred vision, convulsions, collapse, and unconsciousness. Physical examination findings include core temperature usually over 40°C, hot skin, initially covered with perspiration, then later it dries; strong pulse initially; widened pulse pressure; blood pressure is slightly elevated at first, but hypotension develops later; tachycardia; and hyperventilation. Exertional heat stroke may present with sudden collapse and loss of consciousness followed by irrational behavior. Sweating may not be present. Multiorgan dysfunction or failure is a common and serious complication.

B. Laboratory Findings

Laboratory evaluation may reveal dehydration; leukocytosis; elevated blood urea nitrogen (BUN); hyperuricemia; hemococoncentration; acid-base abnormalities (lactic acidosis, respiratory alkalosis); decreased serum glucose, sodium, calcium, and phosphorus; thrombocytopenia, fibrinolysis, and coagulopathy; elevated creatine kinase (CK); elevatedaminotransferase levels and liver dysfunction; and elevated cardiac markers. Urine is concentrated, with proteinuria, hematuria, tubular casts, and myoglobinuria. Potassium may be high or low. ECG findings may include ST–T changes consistent with myocardial ischemia. Pco₂ may be < 20 mm Hg.

Treatment

Treatment is aimed at rapidly reducing the core temperature (within 1 hour) while supporting circulatory and organ system function to prevent irreversible tissue damage and death. Clinicians must assess for possibility of concurrent conditions (infection, trauma, and drug effects, including adverse side effects, withdrawal, or overdose). Circulatory failure in heat-related illness is mostly due to shock from relative or absolute hypovolemia. Intravascular volume status should be assessed and managed early to reduce the risk of hypovolemic shock. Central venous monitoring is useful to guide volume status. Oral or intravenous fluid administration must be provided to ensure adequate urinary output. Fluid output should be monitored through the use of an indwelling urinary catheter.

Cooling methods are evaporative and conductive-based. Systemic review of the research found that there are comparable effects of these cooling methods whether used singly or in combination. No single cooling method is found to be superior. Choice of cooling method depends on which can be instituted the fastest with the least compromise to the overall care of the patient.

Evaporative cooling is a noninvasive, effective, quick and easy way to reduce temperature. Large fans circulate the room air while the entire undressed body is sprayed with lukewarm water (20°C). Inhalation of cool air or oxygen is also effective.

Conductive-based cooling involves cool fluid infusion, lavage, ice packs, and immersion into ice water or cool water. Intravascular heat exchange catheter systems as well as hemodialysis using cold dialysate (30–35°C) have been successful in reducing core temperature. Research suggests that brain cooling may lessen cerebrovascular injury from heat stroke.
Shivering must be avoided because it inhibits the effectiveness of cooling by increasing internal heat production. Medications that can be used to suppress shivering include magnesium, quick-acting opioid analgesics, benzodiazepines, and quick-acting anesthetic agents. Skin massage is recommended to prevent cutaneous vasoconstriction. Antipyretics (aspirin, acetaminophen) have no effect on environmentally induced hyperthermia and are contraindicated. Treatment should be continued until the rectal temperature drops to 39°C.

**Prognosis**

Multiorgan dysfunction is the usual cause of heat stroke–related death, and it can be predicted by elevated creatine kinase, metabolic acidosis, coagulopathy and elevated liver enzymes. Multiorgan dysfunction, rhabdomyolysis, acute respiratory distress syndrome (ARDS), and inflammation may continue after temperature is normalized. Following respiratory distress syndrome (ARDS), and inflammation enzymes. Kinase, metabolic acidosis, coagulopathy and elevated liver related death, and it can be predicted by elevated creatine may continue after temperature is normalized. Following heat stroke, immediate reexposure should be avoided. Sensitivity to high environmental temperature may persist for prolonged periods.

**When to Admit**

- All patients with suspected heat stroke must be admitted to the hospital for close monitoring.
- Monitoring includes vital signs, temperature, and cardiac rhythm, and observation for potential complications of metabolic abnormalities, cardiac arrhythmias, coagulopathy, ARDS, hypoglycemia, seizures, organ dysfunction, and infection.

**General Considerations**

**A. Classification**

Burns are classified by extent, depth, patient age, and associated illness or injury. Accurate estimation of burn size and depth is important since this figure will quantify the parameters of resuscitation.

1. **Extent**—In adults, the “rule of nines” (Figure 37–2) is useful for rapidly assessing the extent of a burn. It is important to view the entire patient to make an accurate assessment of skin findings on initially and on subsequent examinations. One rule of thumb is that the palm of an open hand constitutes 1% total body surface area in adults. Only second- and third-degree burns are included.
in calculating the total burn surface area, since first-degree burns usually do not represent significant injury in terms of prognosis or fluid and electrolyte management. However, first- or second-degree burns may convert to deeper burns, especially if treatment is delayed or bacterial colonization or superinfection occurs.

2. **Depth**—Judgment of depth of injury is difficult. The first-degree burn may be red or gray but will demonstrate excellent capillary refill. First-degree burns are not blistered initially. If the wound is blistered, this represents a partial-thickness injury to the dermis, which is referred to as a second-degree burn. As the degree of burn is progressively deeper, there is a progressive loss of adnexal structures, referred to as a third-degree burn. Hairs can be easily extracted or are absent, sweat glands become less visible, and the skin appears smoother.

Deep second- and third-degree burns are treated in a similar fashion. Neither will heal appropriately without early debridement and grafting; the resultant skin is thin and scarred.

**B. Survival after Burn Injury**

The Prognostic Burn Index is the sum of the patient’s age and percentage of full thickness or deep partial thickness burn. An additional 20% mortality is added if inhalation injury is present. The Prognostic Burn Index is most useful at the extremes of age. Transfer to a burn unit is indicated for large burn size, circumferential burn, or burn involving a joint or high-risk body part, and patients with comorbidities. Mortality rates have been significantly reduced due to treatment advances including improvements in wound care, treatment of infection, early burn excision, skin substitute usage, and early nutritional support through parenteral or enteral feeding. Telemedicine consultation with a burn center is an alternative, cost-effective way to access burn specialists when there are barriers that prevent transfer (distance, bed unavailability, travel risks, etc).

**C. Associated Injuries or Illnesses**

Smoke inhalation, associated trauma, and electrical injuries are commonly associated with burns. Smoke inhalation (see Chapter 9) must be suspected when a burn victim is found in an enclosed space, or in close proximity to the fire. Electrical injury (see following section of this chapter) may cause deep tissue burns without significant superficial skin findings and may also produce cardiac arrhythmias that require immediate attention. Severe burns from any source may cause gastrointestinal complications including pancreatitis and stress ulcers.

**D. Systemic Reactions to Burn Injury**

The actual burn injury is only the incipient event leading to cascade of deleterious local tissue and systemic inflammatory reactions causing multisystem organ failure in the severely burned patient. When burns greater than approximately 20% of total body surface area are present, systemic metabolic alterations occur and require intensive support. The inflammatory cascade can result in shock.

**Treatment**

**A. Initial Resuscitation**

1. **Primary survey**—The clinician must proceed with a full trauma assessment, starting with “ABCDE” (airway, breathing, circulation, disability, exposure). **Airway** assessment and management is the first priority. A patient with an inhalation injury needs to be intubated early to maintain airway patency even though he or she may appear to be breathing normally. To assess and support **breathing** and **circulation**, the clinician should administer supplemental oxygen and obtain vascular access for fluid resuscitation simultaneously with initial resuscitation. **Disability** assessment is next followed by complete patient **exposure** and thorough examination to assess the extent of burn and associated injuries. Serial assessments of airway and breathing are necessary since endotracheal intubation or tracheotomy may be needed for major burn victims, particularly those with possible inhalation injury. Generalized edema develops during fluid resuscitation, including edema of the soft tissues of the upper airway and perhaps the lungs as well. Chest radiographs are typically normal initially but may develop an ARDS picture in 24–48 hours with severe inhalation injury. The use of corticosteroids or routine use of antibiotic therapy is not indicated.

2. **Airway control**—Early intubation is recommended before airway edema occurs in cases of smoke inhalation or direct thermal injury to the upper airway (look for singed eyebrows or facial hair, carbonaceous sputum).

3. **Vascular access**—Large bore peripheral venous catheter access should be established. Femoral lines provide good temporary access during resuscitation if central venous access is needed. Intraosseous access can be obtained if venous access is unsuccessful or contraindicated. **Venous access catheters placed in the emergency department should be changed within 24 hours because of the high risk of non-sterile placement.** An arterial line is useful for monitoring mean arterial pressure and for drawing serial blood gases and other laboratory tests in critically ill patients.

4. **Fluid resuscitation**—Generalized capillary leak results from burn injury over more than 20% of total body surface area. This often necessitates replacement with large volumes of crystalloid. There are many guidelines for fluid resuscitation. The **Parkland formula** relies on the use of lactated Ringer injection. The fluid requirement in the first 24 hours is estimated as 4 mL/kg body weight per percent of body surface area burned. Half the calculated fluid is given in the first 8-hour period. The remaining fluid, divided into two equal parts, is delivered over the next 16 hours. An extremely large volume of fluid may be required. For example, an injury over 40% of the total body surface area in a 70-kg victim may require 11.2 L in the first 24 hours [4 mL x 40(%) x 70 (kg) = 11,200 mL]. The first 8-hour period is measured from the hour of injury. These guidelines may be inadequate, since crystalloid solutions alone may be insufficient to restore cardiac preload during the period of burn shock. Deep electrical burns and inhalation injury increase the fluid requirement.
Adequacy of resuscitation is determined by clinical parameters, including urinary output and specific gravity, blood pressure, pulse, temperature, and central venous pressure. Overly aggressive crystalloid administration must be avoided in patients with pulmonary injury or cardiac dysfunction, since significant pulmonary edema can develop in patients with normal pulmonary capillary wedge and central venous pressures. A Foley catheter is essential for monitoring urinary output. Diuretics have no role in this phase of patient management unless fluid overload has occurred.

The need for fluid replacement of more than 150% of calculated values indicates possible unrecognized injury, possible comorbidities, and a worse prognosis.

B. Management

1. Chemoprophylaxis

A. Tetanus immunization—For all burns deeper than superficial thickness, tetanus immunization must be updated. Tetanus toxoid-containing vaccine should be given intramuscularly to all patients with wounds regardless of how recently the patient received tetanus immunization. In addition, if a patient has not completed the recommended three doses of primary immunization or this is unknown, then tetanus immunoglobulin should also be administered intramuscularly in a different site than the tetanus toxoid. (See Chapter 33)

B. Antibiotics—All nonsuperficial depth wounds should be covered with topical antibiotics. Prophylaxis with systemic antibiotics is not indicated.

2. Surgical management

A. Abdominal compartment syndrome—Abdominal compartment syndrome is emerging as a potentially lethal condition in severely burned patients, even if abdominal decompensation is performed. Markedly increased intrabdominal pressures can cause pulmonary damage and multisystem organ failure. Only 40% of patients with this complication survive. Bladder pressures over 30 mm Hg establish the diagnosis in at-risk patients. Surgical abdominal decompensation may be indicated to improve ventilation and oxygen delivery, but even after this surgery, survival remains low.

B. Escharotomy—As edema fluid accumulates, ischemia may develop under any constricting eschar of an extremity, neck, chest, or trunk if the full-thickness burn is circumferential. Escharotomy incisions through the anesthetic eschar can save life and limb and can be performed in the emergency department or operating room.

C. Fasciotomy—Similar to escharotomy, fasciotomy is indicated to prevent further soft tissue, vascular, and nerve damage when soft tissue edema produces high pressures in the deep tissue compartments in the arms and legs since these compartments are divided by unyielding fascia.

D. Debridement, dressings, and topical and systemic antibiotic therapy—Minor burn wounds should be debrided at the bedside to determine the depth of the burn and then thoroughly cleansed. Thereafter, the wound should be debrided daily and dressed with a topical antibiotic and a wound dressing. Patient compliance and adequate pain treatment is essential for successful outpatient treatment. The wound should be reevaluated by the treating clinician within 24–72 hours to evaluate for signs of infection.

The goal of burn wound management is to protect the wound from desiccation and avoid further injury or infection. Regular and thorough cleansing of burned areas is a critically important intervention in burn units. Minor burn wounds (first- and superficial second-degree types, partial thickness) will spontaneously reepithelialize in 7–10 days. Topical wound agents should be applied. Topical antibiotic wound agents are painless, easy to apply, and effective against most skin pathogens.

For severely burned patients, early excision and grafting of burned areas may be performed as soon as 24 hours after burn injury or when the patient can hemodynamically tolerate the excision and grafting procedure. Meticulous prevention of infections, seromas, hypergranulation tissue formation, and malnutrition all decrease the time to complete wound healing in skin-grafted patients. Skin autograft is the most definitive treatment. Prevention of autograft infection is paramount since autograft loss is most commonly due to autograft infection.

Systemic infection remains a leading cause of morbidity among patients with major burn injuries, with nearly all severely burned patients having one or more septicemic episodes during the hospital course. Healthcare-associated infections are increasingly common. Routine use of blood culture in the severely burned population is indicated to elucidate systemic blood infections that do not manifest these clinical predictors of sepsis.

E. Wound closure—The goal of therapy after fluid resuscitation is rapid and stable closure of the wound. Wounds that will not heal spontaneously in 7–10 days (ie, deep second-degree or third-degree burns) are best treated by excision and autograft.

With severe burns, skin substitution with cultured grafts can be lifesaving. However, although the replaced dermis does have nearly normal histologic dermal elements, there are no adnexal structures present and very few, if any, elastic fibers. Wound infection is the top cause of skin graft rejection and failure.

C. Patient Support

Burn patients require extensive supportive care, both physiologically and psychologically. It is important to maintain normal core body temperature and avoid hypothermia (by maintaining environmental temperature at or above 30°C) in patients with burns over more than 20% of total body surface area. Respiratory injury, sepsis, and multiorgan failure are common. Burn patients require careful assessment and provision of optimal nutritional needs since their metabolism is higher and they require more energy, nutrients, and antioxidants for wound healing. Enteral feedings may be started once the ileus of the resuscitation period has resolved, usually the day after the...
injury. There is often a markedly increased metabolic rate after burn injury, due in large part to whole body synthesis and increased fatty acid substrate cycles. Early aggressive nutrition (by parenteral or enteral routes) reduces infections, recovery time, noninfectious complications, length of hospital stay, long-term sequelae, and mortality.

Careful control of the postinjury blood glucose has been associated with improved hepatic function and better survival after severe burns. Occasionally, ARDS or respiratory failure unresponsive to maximal ventilatory support may develop in burn patients. In addition, the incidence of venous thromboembolism is high among burn patients.

Prevention of long-term scars remains a formidable problem in seriously burned patients. Long-term sequelae can be reduced by burn specialist consultation either directly or via telemedicine, prevention of infection, early nutrition, early aggressive rehabilitation, compressive garments, and early and continual psychological support.

## Prognosis

Prognosis depends on the extent and location of the burn tissue damage, associated injuries, comorbidities, and complications. Hyperglycemia from poor glucose control is a predictor of worse outcomes. Psychiatric support may be necessary following burn injury.

## When to Admit

- All burn patients require extensive supportive care, both physiologically and psychologically.
- Patients with significant burns (based on location and extent), comorbidities, and suboptimal home situations must be admitted to the hospital for close monitoring. Burn center consultation can advise which patients require transfer and which can be managed via telemedicine/telephone consultation.
- Monitoring includes vital signs, wound care, and observation for potential complications of electrolyte abnormalities, acute kidney injury, hepatic failure, cardiopulmonary compromise, hypoglycemia, and infection.

## ELECTRICAL INJURY

### ESSENTIALS OF DIAGNOSIS

- Extent of injury is determined by the type, amount, duration, and pathway of electrical current.
- Resuscitation must be attempted before assuming the electrical injury victim is dead; clinical findings are unreliable.
- Skin findings may be misleading and are not indicative of the degree of deeper tissue injury.

### General Considerations

Electricity-induced injuries are common and most are preventable. These inquiries occur by exposure to electrical current of low voltage, high voltage, or lightning. Electrical current type is either alternating current (AC) or direct current (DC). Electricity causes acute damage by direct tissue damage, muscle tetany, direct thermal injury and coagulation necrosis, and associated trauma.

**Alternating current (AC)** is bidirectional electrical flow that reverses direction in a sine wave pattern. This may cause muscle tetany, which prolongs the duration and amount of current exposure. AC current can be low voltage or high voltage. **Low voltage** (< 1000 V) is typically household AC current that ranges in severity from minor injury to significant damage and death. **High voltage** (> 1000 V) is most often related to occupational exposure and is associated with deep tissue damage and higher morbidity and mortality. **Direct current (DC)** is unidirectional electrical flow (eg, that associated with lightning, batteries, and automotive electrical systems). It is more likely to cause a single intense muscle contraction and asystole. **Lightning** differs from other high-voltage electrical shock in that lightning is massive DC current of millions of volts lasting a very brief duration (a small fraction of a second).

The extent of damage depends on the following factors: voltage (high or low, whether greater or lesser than 1000 volts), current type, tissue resistance, moisture, pathway; duration of exposure; associated trauma and comorbidities. Current is the most important determinant of tissue damage. Current passes through the tissues of least resistance, and this energy produces heat causing direct thermal injury. Tissue resistance varies throughout the body. Nerve cells are the most vulnerable, and bone is the most resistant to electrical current. Skin resistance depends on thickness and condition of the skin. The entrance and exit points are the most damaged. Current passing through skeletal muscle can cause muscle necrosis and contractions severe enough to result in bone fracture.

### Clinical Findings

Electrical burns are of three distinct types: flash (arcing) burns, flame (clothing) burns, and the direct heating effect of tissues by the electrical current. The latter lesions are usually sharply demarcated, round or oval, painless yellow-brown areas (Joule burn) with inflammatory reaction.

---

---
Skin damage does not correlate with the degree of injury. Significant subcutaneous damage can be accompanied by little skin injury, particularly with larger skin surface area electrical contact. Symptoms and signs may range from tingling, superficial skin burns, and myalgias to coma, paralysis, massive tissue damage, or death. Not all electrical injuries cause skin damage; only very minor skin damage may be present with massive internal injuries. The presence of entrance and exit burns signifies an increased risk of deep tissue damage. Resuscitation must be initiated on all victims of electrical injury since clinical findings are deceptive and unreliable. A victim of electrical current injury may appear dead due to dysrhythmia, respiratory arrest, or autonomic dysfunction resulting in pupils that are fixed, dilated, or asymmetric.

Complications
Complications include dysrhythmias, altered mental status, seizures, paralysis, headache, pneumothorax, vascular injury, tissue edema and necrosis, compartment syndrome, associated traumatic injuries, rhabdomyolysis, acute kidney injury, hypovolemia from third spacing, infections, and acute or delayed cataract formation.

Treatment
A. Emergency Measures
The patient must be assessed and treated as a trauma victim since associated traumatic injuries are common. The victim must be safely separated from the electrical current prior to initiation of CPR or other treatment. The rescuer must be protected. Separate the victim using nonconductive implements, such as dry clothing. Resuscitation must then be initiated since clinical findings of death are unreliable.

B. Hospital Measures
The initial assessment involves airway, breathing, and circulation followed by a full trauma protocol. Fluid resuscitation is important to maintain adequate urinary output. Initial evaluation includes cardiac monitoring and ECG, complete blood count, electrolytes, renal function tests, liver biochemical tests, urinalysis, urine myoglobin, serum creatine kinase, and cardiac enzymes. ECG does not show typical patterns of ischemia since the electrical damage is epicardial. Victims must be evaluated for hidden injury.

Electrical burn injury remains the most underrecognized and devastating burn injury, sometimes leading to amputations (often because of unrecognized compartment syndromes) and acute kidney injury, resulting in part from rhabdomyolysis (see Chapter 22). Superficial skin may appear deceivingly benign, leading to a delayed or completely overlooked diagnosis of deep tissue injury. When electrical injury occurs, extensive deep tissue necrosis should be suspected. Deep tissue necrosis leads to profound tissue swelling and this in turn results in the high risk of a compartment syndrome. Early debridement of devitalized tissues and tetanus prophylaxis may reduce the risks of infection. In pregnant patients exposed to electrical injury, the fetus may sustain intrauterine growth retardation, fetal distress, and fetal demise. Fetal monitoring is recommended.

Pain management is important before, during, and after initial treatment and rehabilitation. Multimodal approach to pain is the most effective. Interventions include medications (opioids, acetaminophen, nonsteroidal anti-inflammatory drugs), heat therapy, massage, and cognitive-behavioral therapy.

Prognosis
Prognosis depends on the degree and location of electrical injury, initial tissue damage, associated injuries, comorbidities, and complications. Psychiatric support may be necessary following lightning or severe electroshock exposures.

When to Refer
Surgical specialists may be needed to perform fasciotomy for compartment syndrome or devitalized tissue debridement or microvascular reconstruction.

When to Admit
Indications for hospitalization include high voltage exposure; dysrhythmia or ECG changes; large burn; neurologic, pulmonary, or cardiac symptoms; suspicion of significant deep tissue or organ damage; transthoracic current pathway; history of cardiac disease or other significant comorbidities or injuries; and need for surgery.

RADIATION EXPOSURE
Exposure to radiation may occur from environmental, occupational, medical care, accidental, or intentional (ie, terrorism) exposure. With advancements in nuclear technology in the fields of medicine, energy, and industry, there is a growing risk of radiation exposure to patients, occupational workers, and the public. The extent of damage due to radiation exposure depends on the type, quantity, and duration of radiation exposure; the organs exposed; the degree of disruption to DNA; metabolic and cellular function; and the age, underlying condition, susceptibility, and accumulative exposures of the victim.

Professionals who work with radiation or its victims must have a basic understanding of radiation physics in order to identify risk, manage exposure, and minimize preventable spread of exposure. Radiation is energy waves or particles that travel through space. These energetic waves or particles radiate (move outward in all directions) from the source. Radiation occurs from both nonionizing and ionizing radiation sources. Nonionizing radiation is low energy, resulting in injuries related to local thermal damage (ie, microwave, ultraviolet, visible light and radio-wave). Ionizing radiation is high energy, causing bodily damage in several ways (ie, cellular disruption, DNA damage, and mutations). Ionizing radiation is either electromagnetic (ie, x-rays and gamma rays) or particulate (ie, alpha or beta particles, neutrons, and protons). Exposure may be external, internal, or both.

In acute radiation exposure, medical care includes close monitoring of the gastrointestinal, cutaneous, hematologic, and cerebrovascular symptoms and signs from initial exposure and over time.

Radiation exposure results in early and delayed effects. Early effects involve damage of the rapidly dividing cells (ie, the mucosa, skin, and bone marrow). This may be manifested as nausea, vomiting, and decreased lymphocyte count over hours to days after exposure. Delayed effects include malignancy, reproduction abnormalities, liver, kidney, and central nervous system and immune system dysfunction.

**ACUTE & DELAYED EFFECTS OF RADIATION EXPOSURE ON NORMAL TISSUES**

**Clinical Findings**

**A. Injury to Superficial Structures**

Acute radiation exposure to the skin and mucous membranes may cause erythema, epilation, destruction of fingernails, or epidermolysis, and burns that appear similar to thermal burns but usually have a slower onset and course. Chronic damage includes skin scarring, atrophy, telangiectasis, and xerostomia. Radiation effects on the eyes include cataracts, dry eye syndrome, and retinopathy.

**B. Injury to Deep Structures**

Hematopoietic system radiation exposure causes injury to the bone marrow that may vary from transient decreases to complete destruction of blood elements. Lymphocytes are most sensitive, followed by polymorphonuclear leukocytes; erythrocytes are the least sensitive. Hematopoietic effects consisting of anemia, thrombocytopenia, and bone marrow suppression can occur 1–3 weeks after radiation exposure. Bone marrow failure is the main cause of death within the first few months following exposure.

**Nervous system** structures are sensitive to radiation. The brain and spinal cord are much more sensitive than the peripheral nerves to the acute and delayed effects of radiation.

**Cardiovascular system** effects of ionizing radiation result in damage to the heart and coronary arteries. Smaller vessels (the capillaries and arterioles) are more susceptible to damage than larger blood vessels. Delayed effects from radiation include obliterator endarteritis; coronary artery disease; pericarditis with effusion; or constrictive pericarditis, which may occur months or years later. Myocarditis is less common.

**Pulmonary system** radiation with high or repeated moderate doses of radiation may cause pneumonitis or pulmonary fibrosis, which is often delayed for weeks or months.

**Gastrointestinal system** radiation results in mucositis and mucosal edema within hours or days after exposure. Symptoms include odynophagia, anorexia, nausea, vomiting, dehydration, and weakness. High doses of radiation inhibit gastric secretion and cause inflammation and ulceration of the bowels. Delayed effects include hepatitis, liver dysfunction, and intestinal stenosis. The stomach and colon are the gastrointestinal organs most at risk for cancer induction due to internal radiation.

**Urogenital system** radiation effects are dose-dependent, varying from transient decrease in fertility to permanent sterility, chromosomal aberrations, fetal death, or demise. Moderate to heavy irradiation of the embryo results in injury to the fetus or in embryonic death and spontaneous abortion. Microcephaly and other congenital abnormalities may occur in children exposed in utero, especially if the fetus was exposed during early pregnancy. Nephritis and kidney dysfunction may occur as immediate or delayed effects.

**Endocrine system** organs are relatively resistant to low or moderate doses of radiation. The thyroid gland is the endocrine gland at highest risk for cancer induction from internal radiation exposure. Delayed effects of radiation include thyroid dysfunction (hypothyroidism).

**C. Systemic Reaction (Acute Radiation Syndrome)**

Clinicians must be educated to recognize and treat acute radiation sickness also referred to as acute radiation syndrome. Acute radiation syndrome is due to an exposure to high doses of ionizing radiation over a brief time course. The symptom onset is within hours to days depending on the dose. Symptoms include anorexia, nausea, vomiting, weakness, exhaustion, latency and, in some cases, prostration; these symptoms may occur singly or in combination. Dehydration, anemia, and infection may follow. The Centers for Disease Control and Prevention offers web-based information for clinicians regarding acute radiation syndrome (http://emergency.cdc.gov/radiation/arphysicianfactsheet.asp).

**Therapeutic Radiation Exposure**

Radiation therapy has been a successful component to treating many malignancies. This growing population of
cancer survivors treated with radiation therapy is an important resource to review and quantify associations between radiation therapy and risk of long-term adverse health and quality of life outcomes. These radiation-treated cancer survivors have a higher risk of development of a second malignancy; obesity; and pulmonary, cardiac and thyroid dysfunction as well as an increased overall risk for chronic health conditions and mortality. Ongoing study of childhood cancer survivors is needed to establish long-term risks and to evaluate the impact of newer techniques such as conformal radiation therapy or proton-beam therapy.

Medical Imaging Radiation Exposure
Medical imaging with ionizing radiation exposure (eg, computed tomography [CT] and nuclear medicine studies) has dramatically increased over the past two decades. In addition, researchers have found that the radiation dose for the same study varies significantly among different machines and different clinicians, within and across institutions, with radiation doses varying by as much as a factor of 10. This finding highlights the urgent safety need for standardization and regulation of radiation dosing for medical diagnostics.

Clinicians and patients must be aware of the dangers of radiation when deciding on an imaging test. The risks and benefits must be carefully weighed. All patients should keep records of their cumulative medical imaging radiation exposures, as well as copies of the medical images and their interpretations. The American College of Radiology website offers additional safety information (http://www.radiologyinfo.org/en/safety/).

Occupational and Environmental Radiation Exposure
Prevention of occupational radiation exposure involves adequate training of all persons handling radiation as well as creating safety policies and procedures. This will reduce occupational risk of radiation exposure and improve the emergency response to accidental exposure. Prehospital and hospital disaster plans are required for optimal management of radiation exposure. The Radiation Assistance Center (1-865-576-1005) provides 24-hour access to expert information. The Centers for Disease Control and Prevention “Radiation Emergency” website (http://emergency.cdc.gov/radiation/) is a useful resource for professionals.

Treatment
Treatment is focused on decontamination, symptomatic relief, supportive care, and psychosocial support. Specific treatments focus on the dose, route, and effects of exposure.

Prognosis
Prognosis is determined by the radiation dose, duration, and frequency as well as by the underlying condition of the victim. Approximate dose of exposure correlates with the early onset and severity of symptoms (ie, nausea, vomiting, anorexia, abdominal pain, bloody diarrhea, weight loss) and laboratory findings, particularly the decline in lymphocyte count on the complete blood count. Death is usually due to hematopoietic failure (ie, hemorrhage, anemia, and immunosuppression), gastrointestinal mucosal damage, central nervous system damage, widespread vascular injury, or secondary infection.

Carcinogenesis is related to the total dose, duration, accumulation of exposure, and to the susceptibility of the victim. The younger the victim's age at the time of exposure, the greater the risk of acute and long-term damage from radiation. Radiation-related cancer risks persist throughout the exposed person's lifespan. Cancer risk is particularly increased for persons exposed to nuclear radiation (eg, those exposed at Chernobyl, Hiroshima, Nagasaki, and Marshall Island nuclear test detonations). X-rays are classified as carcinogens since exposure causes leukemia and cancers of the thyroid, breast, and lung.

With the increased use of ionizing radiation for medical diagnostics and treatments, there is a growing concern for the iatrogenic increase in radiation-induced cancer risks, especially in children. There are age-related sensitivities to radiation; prenatal and younger age victims are more susceptible to carcinogenesis.

When to Admit
Most patients with significant ionizing radiation exposure require admission for close monitoring and supportive treatment.

Near Drowning

The first requirement of rescue is immediate basic life support and CPR.

Patient must also be assessed for hypothermia, hypoglycemia, concurrent injuries, and medical conditions.

Clinical manifestations are hypoxemia, pulmonary edema, and hypoventilation.
General Considerations

Near drowning describes a submersion event leading to injury. Submersion injury may result in aspiration, laryngospasm, hypoxemia, and acidemia. Drowning describes submersion resulting in death. "Wet" drowning is due to aspiration of fluid or foreign material. "Dry" drowning is due to laryngospasm or airway obstruction. The primary effect is hypoxemia due to perfusion of poorly ventilated alveoli, intrapulmonary shunting, and decreased compliance. A patient may be deceptively asymptomatic during the initial recovery period only to deteriorate or die as a result of acute respiratory failure within the following 12–24 hours.

Preventative measures should be taken to reduce morbidity and mortality from drowning. Conditions that increase risk of submersion injury include the following: (1) use of alcohol or other drugs, (2) extreme fatigue from inadequate water safety skills, (3) poor physical health, (4) hyperventilation, (5) sudden acute illness (eg, hypoglycemia, seizure, dysrhythmia, myocardial infarction, asthma flare), (6) acute trauma (particularly brain or spinal cord injury or both), (7) venous stings or bites, (8) decompression sickness, (9) dangerous water conditions (temperature and turbulence), and (10) carbon monoxide exposure from boat motors.

Clinical Findings

A. Symptoms and Signs

The patient's appearance may vary from asymptomatic, to abnormal vital signs, anxiety, dyspnea, cough, wheezing, trismus, cyanosis, chest pain, dysrhythmia, hypotension, vomiting, diarrhea, headache, altered level of consciousness, neurologic deficit, and apnea. Hypothermia is highly likely with cold water or prolonged submersion.

B. Laboratory Findings

Arterial blood gas results are helpful in determining the degree of injury since initial clinical findings may appear benign. PaO₂ is usually decreased; PaCO₂ may be increased or decreased; pH is decreased. Bedside blood sugar must be checked rapidly. Other testing is based on clinical scenario and may include kidney function, electrolytes, urinalysis, blood count, lactate, cardiac markers, coagulation studies, and alcohol and toxicology levels. Metabolic acidosis is common.

Prevention

Prevention is multi-faceted. Physical barriers (ie, fences) should be placed around pools and other accessible bodies of water. Safety flotation devices and rescue supplies must be immediately available. Use of alcohol or sedative drugs must be avoided during swimming, boating, or other water-based activities. There must be close supervision of those who cannot swim, and personal flotation devices must be worn when boating or water skiing. Swimming lessons, water and boat safety, and basic life support (BLS) education is necessary for anyone involved in water-based activities.

Treatment

A. First Aid

The first requirement of rescue is immediate BLS treatment and CPR. At the scene, immediate measures to combat hypoxemia are critical to improve outcome. BLS care includes sustained ventilation, oxygenation, and circulatory support. Hypothermia and associated trauma, especially brain and cervical spine injury, should always be suspected.

1. Standard BLS is initiated. CPR is provided if pulse and respirations are absent.
2. Patient must be assessed for hypothermia, hypoglycemia, trauma, and concurrent medical conditions.
3. Rescuer should not attempt to drain water from the victim's lungs. The Heimlich maneuver (subdiaphragmatic pressure) should be used only if foreign material airway obstruction is suspected.
4. Resuscitation and BLS efforts must be continued until core temperature reaches 32°C even for seemingly “hopeless” patients. Complete recovery has been reported after prolonged resuscitation of hypothermic patients.

B. Subsequent Management

1. Ensure optimal ventilation and oxygenation—The onset of hypoxemia exists even in the alert, conscious patient who appears to be breathing normally. Oxygen should be administered immediately at the highest available concentration. Oxygen saturation should be maintained at 90% or higher. Endotracheal intubation and mechanical ventilation are necessary for patients unable to maintain an open airway, adequate oxygenation, or ventilation. Continuous positive airway pressure (CPAP) is an effective noninvasive way of reversing hypoxia and hypercarbia in patients with spontaneous respirations and a patent airway. Positive end-expiratory pressure (PEEP) is also effective for treating respiratory insufficiency. Serial physical examinations and chest radiographs should be carried out to detect possible pneumonitis, atelectasis, and pulmonary edema. Bronchodilators may be used to treat wheezing and bronchospasms due to aspiration. Nasogastric suctioning can decompress the stomach, aid in removal of swallowed water, and reduce the risk of aspiration. Antibiotics are reserved for clinical evidence of infection and should not be given prophylactically.

2. Cardiovascular support—Intravascular volume status must be monitored to determine whether vascular fluid replacement and vasopressors or diuretics are needed. Standard therapy for hypotension and pulmonary edema is administered.

3. Correction of blood pH and electrolyte abnormalities—Metabolic acidosis is present in 70% of near-drowning victims, but it is usually corrected through adequate ventilation and oxygenation. Glycemic control improves outcome.

4. Cerebral and spinal cord injury—Central nervous system damage may progress despite apparently adequate treatment of hypoxia and shock. Standard treatment for brain and spinal cord injury must be followed.
5. **Hypothermia**—Core temperature should be measured and managed as appropriate (see Systemic Hypothermia, above).

### General Considerations

Dysbarism and decompression sickness are physiologic problems that result from altitude changes and the environmental pressure effects on gases in the body during underwater descent and ascent, particularly when scuba diving is followed closely by air travel or hiking to high altitudes.

Physics laws describe the mechanisms involved in dysbarism and decompression sickness. As a diver descends, the gases in the body compress; gases dissolve in blood and tissues. During the ascent, gases in the body expand. **Dysbarism** results from gas compression or expansion in parts of the body that are noncompressible or have limited compliance. Lung barotrauma results in pneumomediastinum, pneumothorax, and rupture of the pulmonary vein causing arterial gas embolism. Overpressurization of the bowels may occur, especially if there is underlying pathology. This can result in gastric rupture, bowel obstruction or perforation, or pneumoperitoneum. Less serious conditions can also occur such as mask squeeze, ear squeeze, sinus squeeze, headache, tooth squeeze.

**Decompression sickness** occurs when the ascent is too rapid and gas bubbles form and cause damage depending on their location (eg, coronary, pulmonary, spinal or cerebrovascular). Decompression sickness symptoms depend on the size and number and location of gas bubbles released (notably nitrogen). Risk of decompression sickness depends on the dive details (depth, duration, number of dives, and interval surface time between dives, water conditions) as well as the diver’s age, weight, physical condition, physical exertion, the rate of ascent, and the length of time between the low altitude (scuba dive) and high altitude (air travel or ground ascent). Predisposing factors for decompression sickness include obesity, injury, hypoxia, lung or cardiac disease, right to left cardiac shunt, diver’s overall health, dehydration, alcohol and medication effects, and panic attacks. Decompression sickness also occurs in those who take hot showers after cold dives. Conservative recommendation is to avoid high altitudes (air travel or ground ascent) for at least 24 hours after surfacing from the dive.

### Course & Prognosis

Respiratory damage is often severe in the minutes to hours following a near drowning. With respiratory supportive treatment, improvements typically occur quickly over the first few days following the near drowning. Long-term complications of near drowning may include neurologic impairment, seizure disorder, and pulmonary or cardiac damage. There is a direct correlation between prognosis and the patient’s age, submersion time, rapid prehospital resuscitation and rapid transport to a medical facility, clinical status at time of arrival to hospital, Glasgow Coma Scale score, pupillary reactivity, and overall health assessment (APACHE II score).

### When to Admit

Most patients with significant near drowning or concomitant medical or traumatic conditions require inpatient monitoring for 24 hours following near drowning. This includes continuous monitoring of cardiorespiratory, neurologic, renal and metabolic function. Pulmonary edema may not appear for 24 hours.

---

#### Dysbarism & Decompression Sickness

**Essentials of Diagnosis**

- Symptoms temporally related to recent altitude or pressure changes (ie, scuba diving).
- Early recognition and prompt treatment of decompression sickness are extremely important.
- Patient must also be assessed for hypothermia, hypoglycemia, concurrent injuries, and medical conditions.
- Consultation with diving medicine or hyperbaric oxygen specialist is indicated.
Treatment

Early recognition and prompt treatment are extremely important. Decompression sickness must be considered if symptoms are temporally related to recent diving or altitude or pressure changes within the past 48 hours. Immediate consultation with a diving medicine or hyperbaric oxygen specialist is indicated even if mild symptoms resolved, since relapses with worse outcomes have occurred. Continuous administration of 100% oxygen is indicated and beneficial for all patients. Aspirin may be given for pain. Opioids should be used very cautiously, since these may obscure the response to recompression.

When to Admit

Rapid transportation to a hyperbaric treatment facility for recompression is imperative for decompression sickness. If air transportation is chosen, the aircraft must maintain pressurization near sea level to avoid worsening decompression sickness. The Divers Alert Network is an excellent worldwide resource for emergency advice 24 hours daily for the management of diving-related conditions (www.diversalertnetwork.org). For diving emergencies, call local emergency responder first, then the Divers Alert Network.

HIGH-ALTITUDE ILLNESS

The severity of the high-altitude illness correlates with the rate and height of ascent, and the individual’s susceptibility.

Prompt recognition and medical attention of early symptoms of high-altitude illness should prevent progression.

Immediate descent is the definitive treatment for high-altitude cerebral edema and high-altitude pulmonary edema.

General Considerations

As altitude increases, hypobaric hypoxia results due to a decrease in both barometric pressure and oxygen partial pressure. High-altitude medical problems are due to hypobaric hypoxia at high altitudes (usually > 2000 meters or 6560 feet). Acclimatization occurs as a physiologic response to the rise in altitude and increasing hypobaric hypoxia. Physiologic changes include increases in alveolar ventilation and oxygen extraction by the tissues and increased hemoglobin level and oxygen binding.

High-altitude illness results when the hypoxic stress is greater than the individual’s ability to acclimatize. Risk factors for high-altitude illness include increased physical activity with insufficient acclimatization, inadequate education and preparation, and individual susceptibility (pre-existing medical conditions and medication use), and previous high-altitude illness. The key determinants of high-altitude illness risk and severity include both individual susceptibility factors and altitudinal factors (rapid rate and height of ascent and total change in altitude). Presentations may be acute, subacute, or chronic disturbances that result from hypobaric hypoxia. Acclimatization to altitudes above 5500 m (18,045 ft) is incomplete or physiologically impossible, although individual differences in tolerance to hypoxia exist.

Individual susceptibility factors include underlying conditions such as cardiac and pulmonary dysfunction, patent foramen ovale, blood disorders (ie, sickle cell disease), pregnancy, neurologic condition, recent surgery, and many other chronic medical conditions. Those with symptomatic cardiac or pulmonary disease should avoid high altitudes.

High-altitude illness comprises a spectrum of conditions based on end-organ effects, mostly cerebral and pulmonary. This is a result of fluid shifts from intravascular to extravascular spaces, especially in the brain and lungs. Manifestations of altitude illness include acute and long-term disorders. Acute high-altitude disorders are high-altitude neurologic conditions (acute mountain sickness and high-altitude cerebral edema) and high-altitude pulmonary edema. Long-term exposure to high altitude over months or years with inadequate acclimatization can result in subacute mountain sickness and chronic mountain sickness (Monge disease). (While subacute mountain sickness and Monge disease are mentioned briefly below, a more detailed discussion can be found in the online version of Current Medical Diagnosis & Treatment.)

1. High-Altitude–Associated Neurologic Conditions (Acute Mountain Sickness & High-Altitude Cerebral Edema)

There is a spectrum of neurologic conditions caused by high altitude, ranging from acute mountain sickness to a more serious form, high altitude cerebral edema.

Acute mountain sickness includes both neurologic and pulmonary symptoms, such as headache (most severe and persistent symptom), lassitude, drowsiness, dizziness, chilliness, nausea and vomiting, facial pallor, dyspnea, and cyanosis. Later symptoms include facial flushing, irritability, difficulty concentrating, vertigo, tinnitus, visual and auditory disturbances, anorexia, insomnia, increased dyspnea and weakness on exertion, increased headaches (due to cerebral edema), palpitations, tachycardia, Cheyne-Stokes breathing, and weight loss. More severe manifestations include cerebral and pulmonary edema (high-altitude cerebral edema and high-altitude pulmonary edema; see below).

High-altitude cerebral edema appears to be an extension of the central nervous system symptoms of acute mountain sickness and results from cerebral vasogenic
edema and cerebral cellular hypoxia. It usually occurs at elevations above 2500 meters (8250 feet) and is more common in unacclimatized individuals. Hallmarks are altered consciousness and ataxic gait. Severe headaches, confusion, truncal ataxia, urinary retention or incontinence, focal deficits, papilledema, nausea, vomiting, and seizures may also occur. Symptoms may progress to obtundation and coma.

2. Acute High-Altitude Pulmonary Edema

High-altitude pulmonary edema is a serious complication of hypoxia-induced pulmonary hypertension. It is the leading cause of death from high altitude illness. The hallmark is markedly elevated pulmonary artery pressure followed by pulmonary edema. It usually occurs at levels above 3000 meters (9840 feet). High altitude increases pulmonary arterial pressure and decreases the oxygen uptake and saturation of blood. Early symptoms may appear within 6–36 hours after arrival at high-altitude area. These include incessant dry cough, shortness of breath disproportionate to exertion, headache, decreased exercise performance, fatigue, dyspnea at rest, and chest tightness. Recognition of the early symptoms may enable the patient to descend before incapacitating pulmonary edema develops. Strenuous exertion should be avoided. An early descent of even 500 or 1000 meters may result in improvement of symptoms. Later, wheezing, orthopnea, and hemoptysis may occur as pulmonary edema worsens. Physical findings include tachycardia, mild fever, tachypnea, cyanosis, prolonged respiration, and rales and rhonchi.

The clinical picture may resemble severe pneumonia. The patient may become confused or comatose. Diagnosis is usually clinical; ancillary tests are nonspecific or unavailable on site. Prompt recognition and medical attention of early symptoms prevent progression.

3. Subacute Mountain Sickness

This occurs most frequently in unacclimatized individuals and at high altitudes for a prolonged period of time. The hypobaric hypoxia results in pulmonary hypertension.

4. Chronic Mountain Sickness (Monge Disease)

This uncommon condition is seen in residents of high-altitude communities who have lost their acclimatization to such a hypobaric hypoxic environment. It is difficult to differentiate from chronic pulmonary disease.

Pre-trip preventive measures include participant education, medical prescreening, pre-trip planning, optimal physical conditioning before travel, and adequate rest and sleep the day before travel. Preventive efforts during ascent include reduced food intake; avoidance of alcohol, tobacco, and unnecessary physical activity during travel; slow ascent to allow acclimatization (300 meters per day); and a period of rest and inactivity for 1–2 days after arrival at high altitude. Mountaineering parties at altitudes of ≥3000 meters or higher should carry a supply of oxygen and medical equipment sufficient for several days. Prophylactic medications may be prescribed if no contraindications exist. Prophylactic low-dose acetazolamide (250–500 mg every 12 hours orally or 500 mg extended-release once to twice daily orally) has been shown to reduce the incidence and severity of acute mountain sickness when started 3 days prior to ascent and continued for 48–72 hours at high altitude. Dexamethasone (4 mg every 12 hours orally beginning on the day of ascent, continuing for 3 days at the higher altitude, and then tapering over 5 days) is an alternative prophylactic medication.

Initial treatment involves oxygen administration by mask. Voluntary periodic hyperventilation will often relieve acute symptoms. Definitive treatment is immediate descent. Descent should be at least 610 meters (2000 feet) and should continue until symptoms improve. Descent is essential if the symptoms are persistent, severe, or worsening or if high-altitude pulmonary edema or high-altitude cerebral edema are present. If immediate descent is not possible, portable hyperbaric chambers can provide symptomatic relief.

Acetazolamide (125–250 mg orally every 8–12 hours, conflicting data as to the optimal dose) remains the most effective medication for treatment of acute mountain sickness and for more severe forms of altitude-related conditions. Adverse reactions include peripheral paresthesias, altered taste of carbonated beverages, polyuria, nausea, drowsiness, erectile dysfunction, and myopia. This is a sulfonamide drug and should be used with caution or avoided in persons with past reactions to this class of drug.

Dexamethasone (dose varies depending on the activity level of the individual, ranging from 2 to 4 mg orally every 6 hours) is effective for treatment of acute mountain sickness and acute cerebral edema; this medication should not be used for prophylaxis and should not be continued beyond 7 days. These medications can be continued for as long as symptoms persist and may be used together in severe cases. In most individuals, symptoms clear within 24–48 hours.

Treatment

Treatment must often be initiated under field conditions. The patient must rest in the semi-Fowler position (head raised), and 100% oxygen must be administered. Immediate descent (at least 610 meters [2000 feet]) is essential. Recompression in a portable hyperbaric bag will temporarily reduce symptoms if rapid or immediate descent is not possible. To conserve oxygen, lower flow rates (2–4 L/min) may be used until the victim recovers or is evacuated to a lower altitude and SaO₂ ≥ 90%. Treatment for ARDS (see Chapter 9) may be required for some patients. Calcium channel blockers and selective phosphodiesterase type 5 (PDE5) inhibitors are effective for symptomatic relief: nifedipine (30 mg slow-release tablets every 12 hours), tadalafil (10 mg by mouth every 12 hours), and sildenafil (50 mg by mouth every 8 hours) are alternatives.
When to Admit

- All patients with high-altitude pulmonary edema or high-altitude cerebral edema must be hospitalized for further observation.
- Hospitalization must also be considered for any patient who remains symptomatic after treatment and descent. Pulmonary symptoms and hypoxia may be worsened by pulmonary embolism, bacterial pneumonia, or bronchitis.

SAFETY OF AIR TRAVEL & SELECTION OF PATIENTS FOR AIR TRAVEL

The medical safety of air travel depends on the nature and severity of the traveler’s preflight condition and factors such as travel duration, frequency and use of inflight exercise, cabin pressurization, availability of medical supplies, and presence of health care professionals on board. In-flight medical emergencies are increasing because there are an increasing number of travelers with preexisting medical conditions. Air travel passengers are susceptible to a wide range of flight-related problems: pulmonary (e.g., hypoxia, gas expansion), vascular (venous thromboembolism, VTE), infectious, cardiovascular, gastrointestinal, ocular, immunologic, syncope, neuropsychiatric, metabolic, trauma, and substance-related. These air-travel risks are higher for those air travelers with preexisting medical conditions: cardiovascular disease, thromboembolic disease, asthma, chronic obstructive pulmonary disease, epilepsy, stroke, recent surgery or trauma, diabetes mellitus, infectious disease, mental illness, and substance dependence. Occupational and frequent flyers are at risk for these as well as accumulative radiation exposure, cabin air quality, circadian disturbance, and pressurization problems.

Hypobaric hypoxia is the underlying etiology of most serious medical emergencies in flight. Despite commercial aircraft pressurization requirements, there is significant hypoxemia, dyspnea, gas expansion, and stress in travelers with underlying serious cardiopulmonary and other conditions. Patients with underlying respiratory or cardiac conditions are at highest risk for problems stemming from hypobaric hypoxia.

Research also demonstrates an association between VTE and air travel. Air travel has a threefold higher risk of VTE, especially severe pulmonary embolism. The VTE risk increases proportionally with the flight duration. Higher risk of VTE is seen in travelers with thrombophilia, those receiving hormonal therapy, and pregnant travelers.

Air travel is not advised for anyone who is incapacitated, or who has an active pneumothorax, class III and IV pulmonary hypertension, acute worsening of an underlying lung disease, or any unstable conditions. The Air Transport Association of America defines an incapacitated passenger as “one who is suffering from a physical or mental disability and who, because of such disability or the effect of the flight on the disability, is incapable of self-care; would endanger the health or safety of such person or other passengers or airline employees; or would cause discomfort or annoyance of other passengers.” Unstable conditions include poorly controlled hypertension, dysrhythmias, angina, valvular disease, congestive heart failure, or psychiatric condition; severe anemia or sickle cell disease; recent myocardial infarction, cerebrovascular accident, or deep venous thrombosis; postsurgery, especially heart surgery (unless approved by surgeon); and any active communicable disease (influenza, tuberculosis, measles, chickenpox, or other communicable virulent infections). Risk of transmission increases when there is close contact to infected passengers.

Pregnancy and Infancy

Pregnancy is a hypercoagulable state with fivefold to tenfold increase in VTE risk. Air travel increases this risk of VTE. Pregnant women may be permitted to fly during the first 8 months of pregnancy unless there is a history of pregnancy complications or premature birth. Infants younger than 1 week old should not be flown at high altitudes or for long distances. There is a higher risk of transmission of infection in-flight for pregnant women and infants due to their weaker immune response. Estimates of air travel radiation exposure are available through the Federal Aviation Administration and vary based on frequency and duration of flights.

Prevention

Air travel complications may be reduced by the following preventive measures: passenger education, passenger prescreening, and in-flight positioning and activity. Prescreening is especially important for those who have had recent surgery or an emergency condition, and those with chronic serious medical conditions. Travelers with pulmonary disease must have preflight medical assessment to determine whether supplemental oxygen is required. Travelers can reduce VTE risk by avoiding constrictive clothing, wearing support hose, changing position frequently, avoiding leg crossing, engaging in frequent in-flight leg exercises, and walking. Low-molecular-weight heparin may be prescribed in travelers at high risk for VTE.
Disorders Related to Environmental Factors

Patients with drug overdoses or poisoning may initially have no symptoms or they may have varying degrees of overt intoxication. The asymptomatic patient may have been exposed to or may have ingested a lethal dose but not yet exhibit any manifestations of toxicity. It is important to: (1) quickly assess the potential danger, (2) consider gut decontamination to prevent absorption, (3) treat complications if they occur, and (4) observe the asymptomatic patient for an appropriate interval.

**Assess the Danger**

If the drug or poison is known, its danger can be assessed by consulting a text or computerized information resource or by calling a regional poison control center. (In the United States, dialing 1-800-222-1222 will direct the call to the regional poison control center.) Assessment will usually take into account the dose ingested; the time since ingestion; the presence of any symptoms or clinical signs; pre-existing cardiac, respiratory, kidney, or liver disease; and, occasionally, specific serum drug or toxin levels. Be aware that the history given by the patient or family may be incomplete or unreliable.

**IMMEDIATE 24-HOUR TOXICOLOGY CONSULTATION**

Call your regional poison control center
U.S. toll-free 1-800-222-1222

**Observation of the Patient**

Asymptomatic or mildly symptomatic patients should be observed for at least 4–6 hours. Longer observation is indicated if the ingested substance is a sustained-release preparation or is known to slow gastrointestinal motility or may cause a delayed onset of symptoms (such as acetaminophen, colchicine, or hepatotoxic mushrooms). After that time, the patient may be discharged if no symptoms have developed. Before discharge, psychiatric evaluation should be performed to assess suicide risk. Intentional ingestions in adolescents should raise the possibility of unwanted pregnancy or sexual abuse.

**THE SYMPTOMATIC PATIENT**

In symptomatic patients, treatment of life-threatening complications takes precedence over in-depth diagnostic evaluation. Patients with mild symptoms may deteriorate rapidly, which is why all potentially significant exposures should be observed in an acute care facility. The following complications may occur, depending on the type of poisoning.

**COMA**

**Assessment & Complications**

Coma is commonly associated with ingestion of large doses of antihistamines (eg, diphenhydramine), benzodiazepines and other sedative-hypnotic drugs, ethanol, opioids, antipsychotic drugs, or antidepressants. The most common cause of death in comatose patients is respiratory failure, which may occur abruptly. Pulmonary aspiration of gastric contents may also occur, especially in victims who are deeply obtunded or convulsing. Hypoxia and hypoventilation may cause or aggravate hypotension, arrhythmias, and seizures. Thus, protection of the airway and assisted ventilation are the most important treatment measures for any poisoned patient.

**Treatment**

**A. Emergency Management**

The initial emergency management of coma can be remembered by the mnemonic ABCD, for Airway, Breathing, Circulation, and Drugs (dextrose, thiamine, and naloxone or flumazenil), respectively.

**1. Airway**—Establish a patent airway by positioning, suction, or insertion of an artificial nasal or oropharyngeal airway. If the patient is deeply comatose or if airway
reflexes are depressed, perform endotracheal intubation. These airway interventions may not be necessary if the patient is intoxicated by an opioid or a benzodiazepine and responds to intravenous naloxone or flumazenil (see below).

2. Breathing—Clinically assess the quality and depth of respiration, and provide assistance if necessary with a bag-valve-mask device or mechanical ventilator. Administer supplemental oxygen, if needed. The arterial blood CO2 tension is useful in determining the adequacy of ventilation. The arterial blood PO2 determination may reveal hypoxemia, which may be caused by respiratory arrest, bronchospasm, pulmonary aspiration, or noncardiogenic pulmonary edema. Pulse oximetry provides an assessment of oxygenation but is not reliable in patients with methemoglobinemia or carbon monoxide poisoning, unless a newer pulse oximetry device capable of detecting these forms of hemoglobin is used (eg, the Masimo pulse CO-oximeter).

3. Circulation—Measure the pulse and blood pressure and estimate tissue perfusion (eg, by measurement of urinary output, skin signs, arterial blood pH). Place the patient on continuous ECG monitoring. Insert an intravenous line, and draw blood for glucose, electrolytes, serum creatinine and liver tests, and possible quantitative toxicologic testing.

4. Drugs

A. Dextrose and thiamine—Unless promptly treated, severe hypoglycemia can cause irreversible brain damage. Therefore, in all obtunded, comatose or convulsing patients, give 50% dextrose, 50–100 mL by intravenous bolus, unless a rapid bedside blood sugar test is available and rules out hypoglycemia. In alcoholic or very malnourished patients who may have marginal thiamine stores, give thiamine, 100 mg intramuscularly or in the intravenous fluids.

B. Opioid antagonists—Naloxone, 0.4–2 mg intravenously, may reverse opioid-induced respiratory depression and coma. It is often given empirically to any comatose patient with depressed respirations. If opioid overdose is strongly suspected, give additional doses of naloxone (up to 5–10 mg may be required to reverse the effects of potent opioids). Note: Naloxone has a shorter duration of action (2–3 hours) than most common opioids; repeated doses may be required, and continuous observation for at least 3–4 hours after the last dose is mandatory. Nalmefene, a newer opioid antagonist, has a duration of effect longer than that of naloxone but still shorter than that of the opioid methadone.

C. Flumazenil—Flumazenil, 0.2–0.5 mg intravenously, repeated as needed up to a maximum of 3 mg, may reverse benzodiazepine-induced coma. Caution: Flumazenil should not be given if the patient has coingested a tricyclic antidepressant or other potential convulsant, is a user of high-dose benzodiazepines, or has a seizure disorder because its use in these circumstances may precipitate seizures. In most circumstances, use of flumazenil is not advised as the potential risks outweigh its benefits. Note: Flumazenil has a short duration of effect (2–3 hours), and resedation requiring additional doses may occur.

HYPOTENSION

Assessment & Complications

Hypotension may be due to poisoning by many different drugs and poisons, including antihypertensive drugs, β-blockers, calcium channel blockers, disulfiram (ethanol interaction), iron, trazodone, quetiapine, and other anticholinergic agents and antidepressants. Poisons causing hypotension include cyanide, carbon monoxide, hydrogen sulfide, aluminum phosphide, arsenic, and certain mushrooms.

Hypotension in the poisoned or drug-overdosed patient may be caused by venous or arterial vasodilation, hypovolemia, depressed cardiac contractility, or a combination of these effects.

Treatment

Most hypotensive patients respond to empiric treatment with repeated 200 mL intravenous boluses of 0.9% saline or other isotonic crystalloid up to a total of 1–2 L; much larger amounts may be needed if the victim is profoundly volume depleted (eg, as with Amanita phalloides mushroom poisoning). Monitoring the central venous pressure (CVP) can help determine whether further fluid therapy is needed. If fluid therapy is not successful, give dopamine or norepinephrine by intravenous infusion. Consider bedside cardiac ultrasound or pulmonary artery catheterization (or both) if hypotension persists.

Hypotension caused by certain toxins may respond to specific treatment. For hypotension caused by overdoses of tricyclic antidepressants or other sodium channel blockers, administer sodium bicarbonate, 50–100 mEq by intravenous bolus injection. Norepinephrine 4–8 mcg/min by intravenous infusion is more effective than dopamine in some patients with overdoses of tricyclic antidepressants or of drugs with predominantly vasodilating effects. For β-blocker overdose, glucagon (5–10 mg intravenously) may be of value. For calcium channel blocker overdose, administer calcium chloride, 1–2 g intravenously (repeated doses may be necessary; doses of 5–10 g and more have been given in some cases). High-dose insulin (0.5–1 units/kg/h intravenously) euglycemic therapy may also be used (see the sections on β-Adrenergic Blockers and Calcium Channel Blockers, below). Intralipid 20% lipid emulsion

HYPOTHERMIA

Assessment & Complications

Hypothermia commonly accompanies coma due to opioids, ethanol, hypoglycemic agents, phenothiazines, barbiturates, benzodiazepines, and other sedative-hypnotics and central nervous system depressants. Hypothermic patients may have a barely perceptible pulse and blood pressure. Hypothermia may cause or aggravate hypotension, which will not reverse until the temperature is normalized.

Treatment

Treatment of hypothermia is discussed in Chapter 37. Gradual rewarming is preferred unless the patient is in cardiac arrest.
has been reported to improve hemodynamics in human case reports or animal studies of intoxication by highly lipid-soluble drugs such as bupivacaine, buspripion, clomipramine, and verapamil.

HYPERTENSION

Assessment & Complications

Hypertension may be due to poisoning with amphetamines, anticholinergics, cocaine, performance-enhancing products (containing caffeine, phenylephrine, ephedrine, or yohimbine), monoamine oxidase (MAO) inhibitors, and other drugs.

Severe hypertension (eg, diastolic blood pressure > 105–110 mm Hg in a person who does not have chronic hypertension) can result in acute intracranial hemorrhage, myocardial infarction, or aortic dissection.

Treatment

Treat hypertension if the patient is symptomatic or if the diastolic pressure is > 105–110 mm Hg—especially if there is no prior history of hypertension.

Hypertensive patients who are agitated or anxious may benefit from a sedative such as lorazepam, 2–3 mg intravenously. For persistent hypertension, administer phenotolamine, 2–5 mg intravenously, or nitroprusside sodium, 0.25–8 mcg/kg/min intravenously. If excessive tachycardia is present, add propranolol, 0.2–0.3 mg/kg/h intravenously, or labetalol, 0.25–8 mcg/kg/min intravenously. Caution: Do not give β-blockers alone, since doing so may paradoxically worsen hypertension as a result of unopposed α-adrenergic stimulation.

ARRHYTHMIAS

Assessment & Complications

Arrhythmias may occur with a variety of drugs or toxins (Table 38–1). They may also occur as a result of hypoxia, metabolic acidosis, or electrolyte imbalance (eg, hyperkalemia, hypokalemia, hypomagnesemia or hypocalcemia), or following exposure to chlorinated solvents or chloral hydrate overdose. Atypical ventricular tachycardia (torsades de pointes) is often associated with drugs that prolong the QT interval.

Treatment

Arrhythmias may be caused by hypoxia or electrolyte imbalance, and these conditions should be sought and treated. If ventricular arrhythmias persist, administer lidocaine or amiodarone at usual antiarrhythmic doses. Note: Wide QRS complex tachycardia in the setting of tricyclic antidepressant overdose (or diphenhydramine or class 1a antiarrhythmic drugs) should be treated with sodium bicarbonate, 50–100 mL intravenously by bolus injection. (See discussion of tricyclic antidepressant poisoning.) Caution: Avoid class 1a antiarrhythmic agents (eg, procainamide, disopyramide), which may aggravate arrhythmias caused by tricyclic antidepressants. Torsades de pointes associated with prolonged QT interval may respond to intravenous magnesium (2 g intravenously over 2 minutes) or overdrive pacing. Treat digitalis-induced arrhythmias with digoxin-specific antibodies (see discussion of cardiac glycoside poisoning).

For tachyarrhythmias induced by chlorinated solvents, chloral hydrate, Freons, or sympathomimetic agents, use propranolol or esmolol (see doses given above in Hypertension section).

SEIZURES

Assessment & Complications

Seizures may be due to poisoning with many poisons and drugs, including amphetamines, antidepressants (especially tricyclic antidepressants, bupropion, and venlafaxine), antihistamines (especially diphenhydramine), antipsychotics, camphor, cocaine, isoniazid (INH), chlorinated insecticides, and theophylline. Massive overdose with acetaminophen has caused seizures. The onset of seizures may be delayed for up to 22 hours after sustained-released bupropion overdose.

Seizures may also be caused by hypoxia, hypoglycemia, hypocalcemia, hyponatremia, withdrawal from alcohol or sedative-hypnotics, head trauma, central nervous system infection, or idiopathic epilepsy.

Prolonged or repeated seizures may lead to hypoxia, metabolic acidosis, hyperthermia, and rhabdomyolysis.

Treatment

Administer lorazepam, 2–3 mg, or diazepam, 5–10 mg, intravenously over 1–2 minutes, or—if intravenous access is not immediately available—midazolam, 5–10 mg intramuscularly. If convulsions continue, administer phenobarbital, 15–20 mg/kg slowly intravenously over no less than 30 minutes. (For drug-induced seizures, phenobarbital is preferred over phenytoin.) Propofol infusion has also been reported effective for some resistant drug-induced seizures.

Seizures due to a few drugs and toxins may require antidotes or other specific therapies (as listed in Table 38–2).

Seizures due to poisoning with many poisons and drugs, including amphetamines, antidepressants (especially tricyclic antidepressants, bupropion, and venlafaxine), antihistamines (especially diphenhydramine), antipsychotics, camphor, cocaine, isoniazid (INH), chlorinated insecticides, and theophylline. Massive overdose with acetaminophen has caused seizures. The onset of seizures may be delayed for up to 22 hours after sustained-released bupropion overdose.

Seizures may also be caused by hypoxia, hypoglycemia, hypocalcemia, hyponatremia, withdrawal from alcohol or sedative-hypnotics, head trauma, central nervous system infection, or idiopathic epilepsy.

Prolonged or repeated seizures may lead to hypoxia, metabolic acidosis, hyperthermia, and rhabdomyolysis.

Assessment & Complications

Hyperthermia may be associated with poisoning by amphetamines (especially methylenedioxymethamphetamine [MDMA; “Ecstasy”]), atropine and other anti-cholinergic drugs, cocaine, salicylates, strychnine, tricyclic antidepressants, and various other medications. Overdoses of serotonin reuptake inhibitors (eg, fluoxetine, paroxetine, sertraline) or their use in a patient taking an MAO inhibitor may cause agitation, hyperactivity, myoclonus, and hyperthermia (“serotonin syndrome”). Antipsychotic agents can cause rigidity and hyperthermia (neuroleptic malignant syndrome [NMS]). (See section on schizophrenia and other psychotic disorders in Chapter 25.) Malignant hyperthermia is a rare disorder associated with general anesthetic agents.

Hyperthermia is a rapidly life-threatening complication. Severe hyperthermia (temperature > 40–41°C) can rapidly cause brain damage and multiorgan failure, including rhabdomyolysis, acute renal failure, and coagulopathy (see Chapter 37).

Treatment

Treat hyperthermia aggressively by removing the patient’s clothing, spraying the skin with tepid water, and fanning. If this is not rapidly effective, as shown by a normal rectal temperature within 30–60 minutes, or if there is significant muscle rigidity or hyperactivity, induce neuromuscular paralysis with a nondepolarizing neuromuscular blocker (eg, rocuronium, vecuronium). Once paralyzed, the patient must be intubated and mechanically ventilated and sedated. While the patient is paralyzed, the absence of visible muscular convulsive movements may give the false impression that brain seizure activity has ceased; bedside electroencephalography may be useful in recognizing continued nonconvulsive seizures.

Dantrolene (2–5 mg/kg intravenously) may be effective for hyperthermia associated with muscle rigidity that does not respond to neuromuscular blockade (ie, malignant hyperthermia). Bromocriptine, 2.5–7.5 mg orally daily, has been recommended for neuroleptic malignant syndrome. Cyproheptadine, 4 mg orally every hour for three or four doses, or chlorpromazine, 25 mg intravenously or 50 mg intramuscularly, has been used to treat serotonin syndrome.

1See text for dosages.
ANTIDOTES & OTHER TREATMENT

ANTIDOTES

Give an antidote (if available) when there is reasonable certainty of a specific diagnosis (Table 38–3). Be aware that some antidotes themselves may have serious side effects. The indications and dosages for specific antidotes are discussed in the respective sections for specific toxins.

DECONTAMINATION OF THE SKIN

Corrosive agents rapidly injure the skin and eyes and must be removed immediately. In addition, many toxins are readily absorbed through the skin, and systemic absorption can be prevented only by rapid action.

Wash the affected areas with copious quantities of lukewarm water or saline. Wash carefully behind the ears, under the nails, and in skin folds. For oily substances (eg, pesticides), wash the skin at least twice with plain soap and shampoo the hair. Specific decontaminating solutions or solvents (eg, alcohol) are rarely indicated and in some cases may paradoxically enhance absorption. For exposure to chemical warfare poisons such as nerve agents or vesicants, some authorities recommend use of a dilute hypochlorite solution (household bleach diluted 1:10 with water), but not in the eyes.

DECONTAMINATION OF THE EYES

Act quickly to prevent serious damage. Flush the eyes with copious amounts of saline or water. (If available, instill local anesthetic drops in the eye before beginning irrigation.) Remove contact lenses if present. Direct the irrigating stream so that it will flow across the eyes after running off the nasal bridge. Lift the tarsal conjunctiva to look for undissolved particles and to facilitate irrigation. Continue irrigation for 15 minutes or until each eye has been irrigated with at least 1 L of solution. If the toxin is an acid or a base, check the pH of the tears after irrigation, and continue irrigation until the pH is between 6 and 8. Special amphoteric solutions (Diphoterine, Previn) have been introduced in Europe for treatment of alkali injuries to the eye.

After irrigation is complete, perform a careful examination of the eye, using fluorescein and a slit lamp or Wood lamp to identify areas of corneal injury. Patients with serious conjunctival or corneal injury should be immediately referred to an ophthalmologist.

GASTROINTESTINAL DECONTAMINATION

Removal of ingested poisons was a routine part of emergency treatment for decades. However, prospective randomized studies have failed to demonstrate improved clinical outcome after gastric emptying. For small or moderate ingestions of most substances, toxicologists generally recommend oral activated charcoal alone without prior gastric emptying; in some cases, when the interval after ingestion has been more than 1–2 hours and the ingestant is non–life-threatening, even charcoal is withheld. Exceptions are large ingestions of anticholinergic compounds and salicylates, which often delay gastric emptying, and ingestion of sustained-release or enteric-coated tablets, which may remain intact for several hours.

Gastric emptying is not generally used for ingestion of corrosive agents or petroleum distillates, because further esophageal injury or pulmonary aspiration may result. However, in certain cases, removal of the toxin may be more important than concern over possible complications. Consult a medical toxicologist or regional poison control center (1-800-222-1222) for advice.

A. Emesis

Emesis using syrup of ipecac can partially evacuate gastric contents if given very soon after ingestion (eg, at work or at home). However, it may increase the risk of pulmonary aspiration and delay or prevent the use of oral activated charcoal. Therefore, it is no longer used in the routine management of ingestions.

B. Gastric Lavage

Gastric lavage is more effective for liquid poisons or small pill fragments than for intact tablets or pieces of mushroom. It is most useful when started within 60 minutes after ingestion. However, the lavage procedure may delay administration of activated charcoal and may stimulate vomiting and pulmonary aspiration in an obtunded patient.

1. Indications—Gastric lavage is sometimes used after very large ingestions (eg, massive aspirin overdose), for collection and examination of gastric contents for identification of the poison, and make it easier to administer charcoal and oral antidotes.

2. Contraindications—Do not use lavage for stuporous or comatose patients with depressed airway protective reflexes unless they are endotracheally intubated beforehand. Some authorities advise against lavage when caustic material has been ingested; others regard it as essential to remove liquid corrosives from the stomach.

3. Technique—in obtunded or comatose patients, the danger of aspiration pneumonia is reduced by performing endotracheal intubation with a cuffed tube before the procedure. Gently insert a lubricated, soft but noncollapsible stomach tube (at least 37–40°F) through the mouth or nose into the stomach. Aspirate and save the contents, and then lavage repeatedly with 50- to 100-mL aliquots of fluid until the return fluid is clear. Use lukewarm tap water or saline.

C. Activated Charcoal

Activated charcoal effectively adsorbs almost all drugs and poisons. Poorly adsorbed substances include iron, lithium, potassium, sodium, mineral acids, and alcohols.

1. Indications—Activated charcoal can be used for prompt adsorption of drugs or toxins in the stomach and intestine. Studies in volunteers show that activated charcoal given alone may be as effective as, or more effective, than ipecac-induced emesis or gastric lavage. However, evidence of benefit in clinical studies is lacking. Administration of charcoal, especially if mixed with sorbitol, can provoke vomiting, which could lead to pulmonary aspiration in an obtunded patient.

2. Contraindications—Activated charcoal should not be used for comatose or convulsing patients unless it can be given by gastric tube and the airway is first protected by a cuffed endotracheal tube. It is also contraindicated for patients with ileus or intestinal obstruction or those who have ingested corrosives for whom endoscopy is planned.

3. Technique—Administer activated charcoal, 60–100 g orally or via gastric tube, mixed in aqueous slurry. Repeated doses may be given to ensure gastrointestinal adsorption or to enhance elimination of some drugs (see below).

D. Catharsis

1. Indications—Cathartics are used by some toxicologists for stimulation of peristalsis to hasten the elimination of unabsorbed drugs and poisons and the activated charcoal slurry. There is no clinical evidence to support their use, and some agents (eg, sorbitol) can provoke vomiting, increasing the risk of pulmonary aspiration.

2. Contraindications and cautions—Do not give a cathartic to patients with suspected intestinal obstruction. Avoid sodium-based cathartics in patients with hypertension, advanced chronic kidney disease, and congestive heart failure and avoid magnesium-based cathartics in patients with advanced chronic kidney disease. Sorbitol (an osmotic cathartic found in some prepackaged activated charcoal slurry products) can cause hypotension and dehydration due to third-spacing and also causes intestinal cramping and vomiting.

E. Whole Bowel Irrigation

Whole bowel irrigation uses large volumes of a balanced polyethylene glycol-electrolyte solution to mechanically cleanse the entire intestinal tract. Because of the composition of the irrigating solution, there is no significant gain or loss of systemic fluids or electrolytes.

1. Indications—Whole bowel irrigation is particularly effective for massive iron ingestion in which intact tablets are visible on abdominal radiographs. It has also been used for ingestions of lithium, sustained-release and enteric-coated tablets, and swallowed drug-filled packets.

2. Contraindications—Do not use in patients with suspected intestinal obstruction. Use with caution in patients who are obtunded or have depressed airway protective reflexes.

3. Technique—Administer a balanced polyethylene glycol-electrolyte solution (CoLyte, GoLYTELY) into the stomach via gastric tube at a rate of 1–2 L/h until the rectal effluent is clear. This may take several hours. It is most effective when patients are able to sit on a commode to pass the intestinal contents.

F. Increased Drug Removal

1. Urinary manipulation—Forced diuresis is hazardous; the risk of complications (pulmonary edema, electrolyte imbalance) usually outweighs its benefits. Acidic drugs (eg, salicylates, phenobarbital) are more rapidly excreted with an alkaline urine. Acidification (sometimes promoted for amphetamines, phencyclidine) is not very effective and is contraindicated in the presence of rhabdomyolysis or myoglobinuria.

2. Hemodialysis—The indications for dialysis are as follows: (1) Known or suspected potentially lethal amounts of a dialyzable drug (Table 38–4); (2) Poisoning with deep coma, apnea, severe hypotension, fluid and electrolyte or acid-base disturbance, or extreme body temperature changes that cannot be corrected by conventional measures; or (3) Poisoning in patients with severe kidney, cardiac, pulmonary, or hepatic disease who will not be able to eliminate toxin by the usual mechanisms.

Continuous renal replacement therapy (also known as continuous venovenous hemodiafiltration or venovenous hemodiafiltration) is of uncertain benefit for elimination
of most poisons but has the advantage of slow removal of the toxin and any accompanying acidosis, and its use has been reported in the management of lithium intoxication.

3. Repeat-dose charcoal—Repeated doses of activated charcoal, 20–30 g orally or via gastric tube every 3–4 hours, may hasten elimination of some drugs (eg, phenytoin, carbamazepine, dapsone) by absorbing drugs excreted into the gut lumen (“gut dialysis”). However, clinical studies have failed to prove better outcome using multiple-dose charcoal. Sorbitol or other cathartics should not be used with each dose, or resulting large stool volumes may lead to dehydration or hypernatremia.

Table 38–4. Recommended use of hemodialysis in poisoning.

| Poison       | Common Indications
|--------------|---------------------
| Carbamazepine| Seizures, severe cardiotoxicity; serum level > 60 mg/L |
| Ethylene glycol | Acidosis, serum level > 50 mg/dL |
| Lithium      | Severe symptoms, level > 4 mEq/L more than 12 hours after last dose. Note: dialysis of uncertain value; CVVHD may be preferable; consult with medical toxicologist. |
| Methanol     | Acidosis, serum level > 50 mg/dL |
| Phenobarbital| Intractable hypotension, acidosis despite maximal supportive care |
| Salicylate   | Severe acidosis, CNS symptoms, level > 100 mg/dL (acute overdose) or > 60 mg/dL (chronic intoxication) |
| Theophylline | Serum level > 90–100 mg/L (acute) or seizures and serum level > 40–60 mg/L (chronic) |
| Valproic acid| Serum level > 900–1000 mg/L or deep coma, severe acidosis |

1See text for further discussion of indications.

CNS, central nervous system; CVVHD, continuous venovenous hemodialysis.

DIAGNOSIS OF POISONING

The identity of the ingested substance or substances is usually known, but occasionally a comatose patient is found with an unlabeled container or the patient is unable or unwilling to give a coherent history. By performing a directed physical examination and ordering common clinical laboratory tests, the clinician can often make a tentative diagnosis that may allow empiric interventions or may suggest specific toxicologic tests.

Physical Examination

Important diagnostic variables in the physical examination include blood pressure, pulse rate, temperature, pupil size, sweating, and the presence or absence of peristaltic activity. Poisonings may present with one or more of the following common syndromes.

A. Sympathomimetic Syndrome

The blood pressure and pulse rate are elevated, though with severe hypertension reflex bradycardia may occur. The temperature is often elevated, pupils are dilated, and the skin is sweaty, though mucous membranes are dry. Patients are usually agitated, anxious, or frankly psychotic.

Examples: Amphetamines, cocaine, ephedrine and pseudoephedrine.

B. Sympatholytic Syndrome

The blood pressure and pulse rate are decreased and body temperature is low. The pupils are small or even pinpoint. Patients are usually obtunded or comatose.

Examples: Barbiturates, benzodiazepines and other sedative hypnotics, γ-hydroxybutyrate (GHB), clonidine and related antihypertensives, ethanol, opioids.

C. Cholinergic Syndrome

Stimulation of muscarinic receptors causes bradycardia, miosis, sweating, and hyperperistalsis as well as bronchorrhea, wheezing, excessive salivation, and urinary incontinence. Nicotinic receptor stimulation may produce initial hypertension and tachycardia as well as fasciculations and muscle weakness. Patients are usually agitated and anxious.

Examples: Carbamates, nicotine, organophosphates (including nerve agents), physostigmine.

D. Anticholinergic Syndrome

Tachycardia with mild hypertension is common, and the body temperature is often elevated. Pupils are widely dilated. The skin is flushed, hot, and dry. Peristalsis is decreased, and urinary retention is common. Patients may have myoclonic jerking or choreoathetoid movements. Agitated delirium is frequently seen, and severe hyperthermia may occur.

Examples: Anticholinergics, antiemetics, antidepressants, antihistamines, tricyclic antidepressants.

Laboratory Tests

The following clinical laboratory tests are recommended for screening of the overdosed patient: measured serum osmolality and osmol gap, electrolytes and anion gap, glucose, creatinine, blood urea nitrogen (BUN), urinalysis (eg, oxalate crystals with ethylene glycol poisoning,
myoglobinuria with rhabdomyolysis), and electrocardiography. Serum acetaminophen and ethanol quantitative levels should be determined in all patients with drug overdoses.

A. Osmol Gap

The osmol gap (see Table 38–5) is increased in the presence of large quantities of low-molecular-weight substances, most commonly ethanol. Common poisons associated with increased osmol gap are acetone, ethanol, ethylene glycol, isopropyl alcohol, methanol, and propylene glycol. **Note:** Severe alcoholic ketoacidosis and diabetic ketoacidosis can also cause an elevated osmol gap resulting from the production of ketones and other low-molecular-weight substances.

B. Anion Gap

Metabolic acidosis associated with an elevated anion gap is usually due to an accumulation of lactic acid or other acids (see Chapter 21). Common causes of elevated anion gap in poisoning include carbon monoxide, cyanide, ethylene glycol, medicinal iron, INH, methanol, metformin, ibuprofen and salicylates. Massive acetaminophen overdose can cause early-onset anion gap metabolic acidosis.

<table>
<thead>
<tr>
<th>Table 38–5. Use of the osmol gap in toxicology.</th>
</tr>
</thead>
</table>

The osmol gap (\(\Delta\text{osm}\)) is determined by subtracting the calculated serum osmolality from the measured serum osmolality.

\[
\text{Calculated osmolality} = 2\text{[Na}^+\text{(mEq/L)]} + \frac{\text{Glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8}
\]

\(\Delta\text{osm} = \text{Measured osmolality} - \text{Calculated osmolality}
\)

Serum osmolality may be increased by contributions of circulating alcohols and other low-molecular-weight substances. Since these substances are not included in the calculated osmolality, there will be a gap proportionate to their serum concentration and inversely proportionate to their molecular weight:

\[
\text{Serum concentration (mg/dL)} = \frac{\Delta\text{osm} \times \text{Molecular weight}}{10}
\]

C. Toxicology Laboratory Testing

A comprehensive toxicology screen is of little value in the initial care of the poisoned patient because results do not return in time to influence clinical management. Specific quantitative levels of certain drugs may be extremely helpful (Table 38–6) however, especially if specific antidotes or interventions (eg, dialysis) would be indicated based on the results.

If a toxicology screen is required, urine is the best specimen. Many hospitals can perform a quick but limited screen for “drugs of abuse” (typically these screens include myoglobinuria with rhabdomyolysis), and electrocardiography. Serum acetaminophen and ethanol quantitative levels should be determined in all patients with drug overdoses.

Table 38–6. Specific quantitative levels and potential therapeutic interventions.1

1Some drugs or toxins may have profound and irreversible toxicity unless rapid and specific management is provided outside of routine supportive care. For these agents, laboratory testing may provide the serum level or other evidence required for administering a specific antidote or arranging for hemodialysis.
only opioids, amphetamines, and cocaine, and some add benzodiazepines, barbiturates, methadone, and tetrahydrocannabinol (marijuana). There are numerous false-positive and false-negative results. For example, synthetic opioids, such as fentanyl, oxycodone, and methadone are usually not detected by routine opiate screening. Blood samples may be saved for possible quantitative testing, but blood is not generally used for screening purposes since it is relatively insensitive for many common drugs, including psychotropic agents, opioids, and stimulants.

**Abdominal Radiographs**
A plain film of the abdomen may reveal radiopaque iron tablets, drug-filled condoms, or other toxic material. Studies suggest that few tablets are predictably visible (eg, ferrous sulfate, sodium chloride, calcium carbonate, and potassium chloride). Thus, the radiograph is useful only if abnormal.

**When to Refer**
Consultation with a regional poison control center (1-800-222-1222) or a medical toxicologist is recommended when the diagnosis is uncertain; there are questions about what laboratory tests to order; when dialysis is being considered to remove the drug or poison; or when advice is needed regarding the indications, dose, and side effects of antidotes.

**When to Admit**
- The patient has symptoms and signs of intoxication that are not expected to clear within a 6–8 hour observation period.
- Delayed absorption of the drug might be predicted to cause a later onset of serious symptoms (eg, after ingestion of a sustained-release product).
- Continued administration of an antidote is required (eg, N-acetylcysteine for acetaminophen overdose).
- Psychiatric or social services evaluation is needed for suicide attempt or suspected drug abuse.

**SELECTED POISONINGS**

**ACETAMINOPHEN**

Acetaminophen (paracetamol in the United Kingdom, Europe) is a common analgesic found in many nonprescription and prescription products. After absorption, it is metabolized mainly by glucuronidation and sulfation, with a small fraction metabolized via the P450 mixed-function oxidase system (2E1) to a highly toxic reactive intermediate. This toxic intermediate is normally detoxified by cellular glutathione. With acute acetaminophen overdose (> 150–200 mg/kg, or 8–10 g in an average adult), hepatocellular glutathione is depleted and the reactive intermediate attacks other cell proteins, causing necrosis. Patients with enhanced P450 2E1 activity, such as chronic alcoholics and patients taking INH, are at increased risk of developing hepatotoxicity. Hepatic toxicity may also occur after prolonged overdosage of acetaminophen—eg, as a result of taking two or three acetaminophen-containing products concurrently or exceeding the recommended maximum dose of 4 g/d for several days.

**Clinical Findings**

Shortly after ingestion, patients may have nausea or vomiting, but there are usually no other signs of toxicity until 24–48 hours after ingestion, when hepatic aminotransferase levels begin to increase. With severe poisoning, fulminant hepatic necrosis may occur, resulting in jaundice, hepatic encephalopathy, advanced chronic kidney disease, and death. Rarely, massive ingestion (eg, serum levels > 500–1000 mg/L [33–66 mmol/L]) can cause early onset of acute coma, seizures, hypotension, and metabolic acidosis unrelated to hepatic injury.

The diagnosis after acute overdose is based on measurement of the serum acetaminophen level. Plot the serum level versus the time since ingestion on the acetaminophen nomogram shown in Figure 38–1. Ingestion of sustained-release products or coingestion of an anticholinergic agent,

![Figure 38-1. Nomogram for prediction of acetaminophen hepatotoxicity following acute overdosage. The upper line defines serum acetaminophen concentrations associated with a risk of hepatotoxicity; the lower line defines serum levels 25% below those expected to cause hepatotoxicity. In uncomplicated cases, the upper line can be used as an indication for therapy with N-acetylcysteine. However, to provide a margin for error in the estimation of the time of ingestion and for patients at higher risk for hepatotoxicity, the lower line is usually used as a guide to treatment. (Adapted, with permission, from Rumack BH et al. Acetaminophen poisoning and toxicity. Pediatrics. 1975 Jun;55(6):871–6.)](image-url)
salicylate, or opioid drug may cause delayed elevation of serum levels and may render the nomogram useless. The nomogram is also not useful after chronic overdose.

### Treatment

#### A. Emergency and Supportive Measures

Administer activated charcoal (see p 1567) if it can be given within 1–2 hours of the ingestion. Although charcoal may interfere with absorption of the oral antidote acetylcysteine, this is not considered clinically significant.

#### B. Specific Treatment

Although the risk is greatest if the serum acetaminophen level is above the upper line on the nomogram (Figure 38–1), many clinicians and published guidelines prefer to use the lower line as a guide to treatment, as it provides an added safety margin. If the precise time of ingestion is unknown or if the patient is at higher risk for hepatotoxicity (eg, alcoholic, liver disease, long-term use of P450-inducing drugs), then some clinicians use a lower threshold for initiation of N-acetylcysteine (in some case reports, a level of 100 mg/L [66 mmol/L] at 4 hours was suggested in very high-risk patients). The antidote N-acetylcysteine can be given orally or intravenously. Oral treatment begins with a loading dose of N-acetylcysteine, 140 mg/kg, followed by 70 mg/kg every 4 hours. Dilute the solution to about 5% with water, juice, or soda. If vomiting interferes with oral N-acetylcysteine administration, consider giving the antidote intravenously (see below). The conventional oral N-acetylcysteine protocol in the United States calls for 72 hours of treatment. However, other regimens have demonstrated equivalent success with 20–48 hours of treatment.

The FDA-approved 21-hour intravenous regimen of acetylcysteine (Acetadote) calls for a loading dose of 150 mg/kg given intravenously over 60 minutes, followed by a 4-hour infusion of 30 mg/kg, and a 16-hour infusion of 100 mg/kg. (If Acetadote is not available, the conventional oral formulation may also be given intravenously using a micropore filter and a slow rate of infusion. Call a regional poison control center or medical toxicologist for assistance.)

Treatment with N-acetylcysteine is most effective if it is started within 8–10 hours after ingestion.

### ACIDS, CORROSIVE

The strong mineral acids exert primarily a local corrosive effect on the skin and mucous membranes. Symptoms include severe pain in the throat and upper gastrointestinal tract; bloody vomitus; difficulty in swallowing, breathing, and speaking; discoloration and destruction of skin and mucous membranes in and around the mouth; and shock. Severe systemic metabolic acidosis may occur both as a result of cellular injury and from systemic absorption of the acid.

Severe deep destructive tissue damage may occur after exposure to hydrofluoric acid because of the penetrating and highly toxic fluoride ion. Systemic hypocalcemia and hyperkalemia may also occur after fluoride absorption, even following skin exposure.

Inhalation of volatile acids, fumes, or gases such as chlorine, fluorine, bromine, or iodine causes severe irritation of the throat and larynx and may cause upper airway obstruction and noncardiogenic pulmonary edema.

### Treatment

#### A. Ingestion

Dilute immediately by giving a glass (4–8 oz) of water to drink. Do not give bicarbonate or other neutralizing agents, and do not induce vomiting. Some experts recommend immediate cautious placement of a small flexible gastric tube and removal of stomach contents followed by lavage, particularly if the corrosive is a liquid or has important systemic toxicity.

In symptomatic patients, perform flexible endoscopic esophagoscopy to determine the presence and extent of injury. CT scan or plain radiographs of the chest and abdomen may also reveal the extent of injury. Perforation, peritonitis, and major bleeding are indications for surgery.

#### B. Skin Contact

Flood with water for 15 minutes. Use no chemical antidotes; the heat of the reaction may cause additional injury.

For hydrofluoric acid burns, soak the affected area in benzalkonium chloride solution or apply 2.5% calcium gluconate gel (prepared by adding 3.5 g calcium gluconate to 5 oz of water-soluble surgical lubricant, eg, K-Y Jelly); then arrange immediate consultation with a plastic surgeon or other specialist. Binding of the fluoride ion may be achieved by injecting 0.5 mL of 5% calcium gluconate per square centimeter under the burned area. (Caution: Do not use calcium chloride.) Use of a Bier-block technique or intraarticular infusion of calcium is sometimes required for extensive burns or those involving the nail bed; consult with a hand surgeon or poison control center (1-800-222-1222).

#### C. Eye Contact

Anesthetize the conjunctiva and corneal surfaces with topical local anesthetic drops (eg, proparacaine). Flood with water for 15 minutes, holding the eyelids open. Check pH with pH 6.0–8.0 test paper, and repeat irrigation, using 0.9% saline, until pH is near 7.0. Check for corneal damage with fluorescein and slit lamp examination; consult an ophthalmologist about further treatment.

#### D. Inhalation

Remove from further exposure to fumes or gas. Check skin and clothing. Treat pulmonary edema.
**ALKALIES**

The strong alkalies are common ingredients of some household cleaning compounds and may be suspected by their “soapy” texture. Those with alkalinity above pH 12.0 are particularly corrosive. Disk (or “button”) batteries are also a source. Alkalies cause liquefactive necrosis, which is deeply penetrating. Symptoms include burning pain in the upper gastrointestinal tract, nausea, vomiting, and difficulty in swallowing and breathing. Examination reveals destruction and edema of the affected skin and mucous membranes and bloody vomitus and stools. Radiographs may reveal evidence of perforation or the presence of radiopaque disk batteries in the esophagus or lower gastrointestinal tract.

**Treatment**

**A. Ingestion**

Dilute immediately with a glass of water. Do not induce emesis. Some gastroenterologists recommend immediate cautious placement of a small flexible gastric tube and removal of stomach contents followed by gastric lavage after ingestion of liquid caustic substances to remove residual material.

Prompt endoscopy is recommended in symptomatic patients to evaluate the extent of damage; CT scanning may also aid in assessment. If a radiograph reveals the location of ingested disk batteries in the esophagus, immediate endoscopic removal is mandatory.

The use of corticosteroids to prevent stricture formation is of no proved benefit and is definitely contraindicated if there is evidence of esophageal perforation.

**B. Skin Contact**

Wash with running water until the skin no longer feels soapy. Relieve pain and treat shock.

**C. Eye Contact**

Anesthetize the conjunctival and corneal surfaces with topical anesthetic (e.g., proparacaine). Irrigate with water or saline continuously for 20–30 minutes, holding the lids open. Amphoteric solutions may be more effective than water or saline and some are available in Europe (Diphoterine, Previn). Check pH with pH test paper, and repeat irrigation for additional 30-minute periods until the pH is near 7.0. Check for corneal damage with fluorescein and slit lamp examination; consult an ophthalmologist for further treatment.

**AMPHETAMINES & COCAINE**

Amphetamines and cocaine are widely abused for their euphoric and stimulant properties. Both drugs may be smoked, snorted, ingested, or injected. Amphetamines and cocaine produce central nervous system stimulation and a generalized increase in central and peripheral sympathetic activity. The toxic dose of each drug is highly variable and depends on the route of administration and individual tolerance. The onset of effects is most rapid after intravenous injection or smoking. Amphetamine derivatives and related drugs include methamphetamine (“crystal meth,” “crank”), MDMA (“Ecstasy”), ephedrine (“herbal ecstasy”), and methcathinone (“cat” or “khat”). Methcathinone derivatives and related synthetic chemicals such as methylenedioxypyrovalerone (MDPV) have become popular drugs of abuse and are often sold as purported “bath salts.” Amphetamine-like reactions have also been reported after use of synthetic cannabinoids (e.g., “Spice” and “K2”). Nonprescription medications and nutritional supplements may contain stimulant or sympathomimetic drugs such as ephedrine, yohimbine, or caffeine (see also Theophylline section).

**Clinical Findings**

Presenting symptoms may include anxiety, tremulousness, tachycardia, hypertension, diaphoresis, dilated pupils, agitation, muscular hyperactivity, and psychosis. Muscle hyperactivity may lead to metabolic acidosis and rhabdomyolysis. In severe intoxication, seizures and hyperthermia may occur. Sustained or severe hypertension may result in intracranial hemorrhage, aortic dissection, or myocardial infarction. Ischemic colitis has been reported. Hyponatremia has been reported after MDMA use; the mechanism is not known but may involve excessive water intake, syndrome of inappropriate antidiuretic hormone (SIADH), or both.

The diagnosis is supported by finding amphetamines or the cocaine metabolite benzoylcegonine in the urine. Note that many drugs can give a false-positive result on the immunoassay for amphetamines.

**Treatment**

**A. Emergency and Supportive Measures**

Maintain a patent airway and assist ventilation, if necessary. Treat seizures as described at the beginning of this chapter (see p 1565). Rapidly lower the body temperature (see hyperthermia, p 1565) in patients who are hyperthermic (temperature > 39–40°C).
Chapter 21. Anticoagulants

B. Specific Treatment

Treat agitation, psychosis, or seizures with a benzodiazepine such as diazepam, 5–10 mg, or lorazepam, 2–3 mg intravenously. Add phenobarbital 15 mg/kg intravenously for persistent seizures. Treat hypertension with a vasodilator drug such as phenolamine (1–5 mg intravenously) or a combined α- and β-adrenergic blocker such as labetalol (10–20 mg intravenously). Do not administer a pure β-blocker such as propranolol alone, as this may result in paradoxic worsening of the hypertension as a result of unopposed α-adrenergic effects.

Treat tachycardia or tachyarrhythmias with a short-acting β-blocker such as esmolol (25–100 mcg/kg/min by intravenous infusion). Treat hyperthermia as described above (see p 1565). Treat hyponatremia as outlined in Chapter 21.

INR is elevated, give phytonadione (vitamin K1), 10–25 mg orally, and increase the dose as needed to restore the prothrombin time to normal. Doses as high as 200 mg/d have been required after ingestion of “superwarfarins.” Give fresh-frozen plasma, prothrombin complex concentrate, or activated Factor VII as needed to rapidly correct the coagulation factor deficit if there is serious bleeding. If the patient is chronically anticoagulated and has strong medical indications for being maintained in that status (eg, prosthetic heart valve), give much smaller doses of vitamin K (1 mg orally) and fresh-frozen plasma (or both) to titrate to the desired prothrombin time.

If the patient has ingested brodifacoum or a related superwarfarin, prolonged observation (over weeks) and repeated administration of large doses of vitamin K may be required.

ANTICONVULSANTS

Anticonvulsants (carbamazepine, phenytoin, valproic acid, and many newer agents) are widely used in the management of seizure disorders and some are also used for treatment of mood disorders or pain.

Phenytoin can be given orally or intravenously. Rapid intravenous injection of phenytoin can cause acute myocardial depression and cardiac arrest owing to the solvent propylene glycol (fosphenytoin does not contain this diluent). Chronic phenytoin intoxication can occur following only slightly increased doses because of zero-order kinetics and a small toxic-therapeutic window. Phenytoin intoxication can also occur following acute intentional or accidental overdose. The overdose syndrome is usually mild even with high serum levels. The most common manifestations are ataxia, nystagmus, and drowsiness. Choreoathetoid movements have been described.

Carbamazepine is used for treatment of trigeminal neuralgia, temporal lobe epilepsy, and other seizure disorders. Intoxication causes drowsiness, stupor and, with high levels, atroventricular block, coma, and seizures. Dilated pupils and tachycardia are common. Toxicity may be seen with serum levels > 20 mg/L (85 mcmol/L), though severe poisoning is usually associated with concentrations > 30–40 mg/L (127–169 mcmol/L). Because of erratic and slow absorption, intoxication may progress over several hours to days.

Valproic acid intoxication produces a unique syndrome consisting of hypernatremia (from the sodium component of the salt), metabolic acidosis, hypocalcemia, elevated serum ammonia, and mild liver aminotransferase elevation. Hypoglycemia may occur as a result of hepatic metabolic dysfunction. Coma with small pupils may be seen and can mimic opioid poisoning. Encephalopathy and cerebral edema can occur.

The newer anticonvulsants gabapentin, levetiracetam, vigabatrin, and zonisamide generally cause somnolence, confusion and dizziness; felbamate can cause crystalluria.
and kidney dysfunction after overdose, and may cause idiosyncratic aplastic anemia with therapeutic use; lamotrigine, topiramate, and tiagabine have been reported to cause seizures after overdose.

### Treatment

#### A. Emergency and Supportive Measures

For recent ingestions, give activated charcoal orally or by gastric tube (see p 1567). For large ingestions of carbamazepine or valproic acid—especially of sustained-release formulations—consider whole bowel irrigation (see p 1567). Multiple-dose activated charcoal and whole-bowel irrigation may be beneficial in ensuring gut decontamination for selected large ingestions.

#### B. Specific Treatment

There are no specific antidotes. Naloxone was reported to have reversed valproic acid overdose in one anecdotal case. Carnitine may be useful in patients with valproic acid–induced hyperammonemia. Consider hemodialysis for massive intoxication with valproic acid or carbamazepine (eg, carbamazepine levels > 60 mg/L [254 mcg/mL] or valproic acid levels > 800 mg/L [5544 mcg/mL]).

---

**Antipsychotic Drugs**

Promethazine, prochlorperazine, chlorpromazine, haloperidol, droperidol, risperidone, olanzapine, ziprasidone, quetiapine, and aripiprazole are used as antipsychotic agents, and sometimes as antiemetics and potentiators of analgesic and hypnotic drugs.

Phenothiazines (particularly chlorpromazine) induce drowsiness and mild orthostatic hypotension in as many as 50% of patients. Larger doses can cause obtundation, miosis, severe hypotension, tachycardia, convulsions, and coma. Abnormal cardiac conduction may occur, resulting in prolongation of QRS or QT intervals (or both) and ventricular arrhythmias. Among the newer agents, quetiapine is more likely to cause coma and hypotension.

With therapeutic or toxic doses, an acute extrapyramidal dystonic reaction may develop in some patients, with spasmodic contractions of the face and neck muscles, extensor rigidity of the back muscles, carpopedal spasm, and motor restlessness. This reaction is more common with haloperidol and other butyrophenones and less common with newer atypical antipsychotics such as ziprasidone, olanzapine, aripiprazole, and quetiapine. Severe rigidity accompanied by hyperthermia and metabolic acidosis (“neuroleptic malignant syndrome”) may occasionally occur and is life-threatening (see Chapter 25).

---

**ARSENIC**

Arsenic is found in some pesticides and industrial chemicals, and arsenic trioxide has recently been reintroduced as a chemotherapeutic agent. A massive epidemic of chronic arsenic poisoning has occurred in Bangladesh due to naturally occurring arsenic in deep aquifers used for drinking water. Symptoms of acute poisoning usually appear within 1 hour after ingestion but may be delayed as long as 12 hours. They include abdominal pain, vomiting, watery diarrhea, and skeletal muscle cramps. Profound dehydration and shock may occur. In chronic poisoning, symptoms can be vague but often include pancytopenia, painful peripheral sensory neuropathy, and skin changes including melanosis, keratosis, and desquamating rash. Urinary arsenic levels may be falsely elevated after certain meals (eg, seafood) that contain large quantities of a nontoxic form of organic arsenic.

### Treatment

#### A. Emergency Measures

After recent ingestion (within 1–2 hours), perform gastric lavage. Activated charcoal is of uncertain benefit because it...
binds arsenic poorly. Administer intravenous fluids to replace losses due to vomiting and diarrhea.

**B. Antidote**

For patients with severe acute intoxication, give dimercaprol injection (British anti-Lewisite, BAL), 10% solution in oil, 3–5 mg/kg intramuscularly every 4–6 hours for 2 days. The side effects include nausea, vomiting, headache, and hypertension. Follow dimercaprol with oral succimer (dimercaptosuccinic acid, DMSA), 10 mg/kg every 8 hours, for 1 week. Consult a medical toxicologist or regional poison control center (1-800-222-1222) for advice regarding chelation.

---

### ATROPINE & ANTICHOLINERGICS

Atropine, scopolamine, belladonna, diphenoxylate with atropine, *Datura stramonium*, *Hyoscyamus niger*, some mushrooms, tricyclic antidepressants, and antihistamines are antimuscarinic agents with variable central nervous system effects. The patient complains of dryness of the mouth, thirst, difficulty in swallowing, and blurring of vision. The physical signs include dilated pupils, flushed skin, tachycardia, fever, delirium, myoclonus, ileus, and flushed appearance. Antidepressants and antihistamines may induce convulsions.

Antihistamines are commonly available with or without prescription. Diphenhydramine commonly causes delirium, tachycardia, and seizures. Massive overdose may mimic tricyclic antidepressant poisoning.

**Treatment**

**A. Emergency and Supportive Measures**

Administer activated charcoal (see p 1567). Tepid sponge baths and sedation, or neuromuscular paralysis in rare cases, are indicated to control high temperatures (see p 1565).

**B. Specific Treatment**

For severe anticholinergic syndrome (eg, agitated delirium), give physostigmine salicylate, 0.5–1 mg slowly intravenously over 5 minutes, with ECG monitoring; repeat as needed to a total dose of no more than 2 mg. **Caution:** Bradycarrhythias and convulsions are a hazard with physostigmine administration, and the drug should be avoided in patients with cardiotoxic effects from tricyclic antidepressants or other sodium channel blockers.

---

### POISONING

**β-ADRENERGIC BLOCKERS**

There are a wide variety of β-adrenergic blocking drugs, with varying pharmacologic and pharmacokinetic properties (see Table 11–7). The most toxic β-blocker is propranolol. Propranolol competitively blocks β₁ and β₂ adrenoceptors and also has direct membrane-depressant and central nervous system effects.

**Clinical Findings**

The most common findings with mild or moderate intoxication are hypotension and bradycardia. Cardiac depression from more severe poisoning is often unresponsive to conventional therapy with β-adrenergic stimulants such as dopamine and norepinephrine. In addition, with propranolol and other lipid-soluble drugs, seizures and coma may occur. Propranolol, oxprenolol, acebutolol, and alpenrolol also have membrane-depressant effects and can cause conduction disturbance (wide QRS interval) similar to tricyclic antidepressant overdose.

The diagnosis is based on typical clinical findings. Routine toxicology screening does not usually include β-blockers.

**Treatment**

**A. Emergency and Supportive Measures**

Attempts to treat bradycardia or heart block with atropine (0.5–2 mg intravenously), isoproterenol (2–20 mcg/min by intravenous infusion, titrated to the desired heart rate), or an external transcutaneous cardiac pacemaker are often ineffective, and specific antidotal treatment may be necessary (see below).

For drugs ingested within an hour of presentation (or longer after ingestion of an extended-release formulation), administer activated charcoal (see p 1567).

**B. Specific Treatment**

For persistent bradycardia and hypotension, give glucagon, 5–10 mg intravenously, followed by an infusion of 1–5 mg/h. Glucagon is an inotropic agent that acts at a different receptor site and is therefore not affected by β-blockade. High-dose insulin (0.5-1 units/kg/h intravenously) along with glucose supplementation has been used to reverse severe cardiotoxicity. Membrane-depressant effects (wide QRS interval) may respond to boluses of sodium bicarbonate (50–100 mEq intravenously) as for tricyclic antidepressant poisoning. Intravenous lipid emulsion (Intralipid 20%, 1.5 mL/kg) has been used successfully in severe propranolol overdose.

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers are used to treat angina pectoris, hypertension, supraventricular tachycardia, migraine, and other disorders. In therapeutic doses, nifedipine, nicardipine, amlopidine, felodipine, isradipine, nisoldipine, and nimodipine act mainly on blood vessels, while verapamil and diltiazem act mainly on cardiac contractility and conduction. However, these selective effects can be lost after acute overdose. Patients may present with bradycardia, atrioventricular (AV) nodal block, hypotension, or a combination of these effects. Hyperglycemia is common due to blockade of insulin release. With severe poisoning, cardiac arrest may occur.

Treatment

A. Emergency and Supportive Measures

For ingested drugs, administer activated charcoal (see p 1567). In addition, whole bowel irrigation (see p 1567) should be initiated as soon as possible if the patient has ingested a sustained-release product.

B. Specific Treatment

If bradycardia and hypotension are not reversed with atropine (0.5–2 mg intravenously), isoproterenol (2–20 mcg/min by intravenous infusion), or a transcutaneous cardiac pacemaker, administer calcium intravenously. Start with calcium chloride 10%, 10 mL, or calcium gluconate 10%, 20 mL. Repeat the dose every 3–5 minutes. The optimum (or maximum) dose has not been established, but many toxicologists recommend raising the ionized serum calcium level to at least twice the normal level. Calcium is most useful in reversing negative inotropic effects and is less effective for AV nodal blockade and bradycardia. Epinephrine infusion (1–4 mcg/min initially) and glucagon (5–10 mg intravenously) have also been recommended. In addition, high doses of insulin (0.5–1 units/kg intravenously) followed by 0.5–1 units/kg/h infusion) along with sufficient dextrose to maintain euglycemia have been reported to be beneficial but there are no controlled studies. Infusion of Intralipid 20% lipid emulsion has been reported to improve hemodynamics in animal models and altered delivery of oxygen to cells (see also Smoke Inhalation in Chapter 9).

Clinical Findings

At low carbon monoxide levels (carboxyhemoglobin saturation 10–20%), victims may have headache, dizziness, abdominal pain, and nausea. With higher levels, confusion, dyspnea, and syncope may occur. Hypotension, coma, and seizures are common with levels > 50–60%. Survivors of acute severe poisoning may develop permanent obvious or subtle neurologic and neuropsychiatric deficits. The fetus and newborn may be more susceptible because of high carbon monoxide affinity for fetal hemoglobin.

Carbon monoxide poisoning should be suspected in any person with severe headache or acutely altered mental status, especially during cold weather, when improperly vented heating systems may have been used. Diagnosis depends on specific measurement of the arterial or venous carboxyhemoglobin saturation, although the level may have declined if high-flow oxygen therapy has already been administered, and levels do not always correlate with clinical symptoms. Routine arterial blood gas testing and pulse oximetry are not useful because they give falsely normal PaO₂ and oxyhemoglobin saturation determinations, respectively. (A specialized pulse oximetry device, the Masimo pulse CO-oximeter, is capable of distinguishing oxyhemoglobin from carboxyhemoglobin.)

Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Remove the victim from exposure. Treat patients with coma, hypotension, or seizures as described at the beginning of this chapter (see pp 1562, 1563, 1565).

B. Specific Treatment

The half-life of the carboxyhemoglobin (CoHb) complex is about 4–5 hours in room air but is reduced dramatically by high concentrations of oxygen. Administer 100% oxygen by tight-fitting high-flow reservoir face mask or endotracheal tube. Hyperbaric oxygen (HBO) can provide 100% oxygen under higher than atmospheric pressures, further shortening the half-life; it may also reduce the incidence of subtle neuropsychiatric sequelae. Randomized controlled studies disagree about the benefit of HBO, but commonly recommended indications for HBO in patients with carbon monoxide poisoning include a history of loss of
Cyanide is a highly toxic chemical used widely in research and commercial laboratories and many industries. Its gaseous form, hydrogen cyanide, is an important component of smoke in fires. Cyanide-generating glycosides are also found in the pits of apricots and other related plants. Cyanide is generated by the breakdown of nitroprusside, and poisoning can result from rapid high-dose infusions. Cyanide is also formed by metabolism of acetonitrile, a solvent found in some over-the-counter fingernail glue removers. Cyanide is rapidly absorbed by inhalation, skin absorption, or ingestion. It disrupts cellular function by inhibiting cytochrome oxidase and preventing cellular oxygen utilization.

► Clinical Findings

The onset of toxicity is nearly instantaneous after inhalation of hydrogen cyanide gas but may be delayed for minutes to hours after ingestion of cyanide salts or cyanogenic plants or chemicals. Effects include headache, dizziness, nausea, abdominal pain, and anxiety, followed by confusion, syncope, shock, seizures, coma, and death. The odor of “bitter almonds” may be detected on the victim’s breath or in vomitus, though this is not a reliable finding. The venous oxygen saturation may be elevated (> 90%) in severe poisonings because tissues have failed to take up arterial oxygen.

► Treatment

A. Emergency and Supportive Measures

Remove the victim from exposure, taking care to avoid exposure to rescuers. For suspected cyanide poisoning due to nitroprusside infusion, stop or slow the rate of infusion. (Metabolic acidosis and other signs of cyanide poisoning usually clear rapidly.)

For cyanide ingestion, administer activated charcoal (see p 1567). Although charcoal has a low affinity for cyanide, the usual doses of 60–100 g are adequate to bind typically ingested lethal doses (100–200 mg).

B. Specific Treatment

In the United States, there are two available cyanide antidote regimens. The conventional cyanide antidote package (Taylor Pharmaceuticals) (Table 38–7) contains nitrates (to induce methemoglobinemia, which binds free cyanide) and thiosulfate (to promote conversion of cyanide to the less toxic thiocyanate). Administer amylnitrite by crushing an ampule under the victim’s nose or at the end of the endotracheal tube, and administer 3% sodium nitrite solution, 10 mL intravenously. Caution: Nitrates may induce hypotension and dangerous levels of methemoglobin. Also administer 25% sodium thiosulfate solution, 50 mL intravenously (12.5 g).

The other approved cyanide treatment in the United States is hydroxocobalamin (Cyanokit, EMD Pharmaceuticals), a newer and potentially safer antidote. The adult dose of hydroxocobalamin is 5 g intravenously (children’s dose is, 70 mg/kg).

CONSIDERATIONS IN HYPERBARIC OXYGEN THERAPY

Other agents to avoid:

Caution: Nitrates may induce hypotension and dangerous levels of methemoglobin. Also administer 25% sodium thiosulfate solution, 50 mL intravenously (12.5 g).

The other approved cyanide treatment in the United States is hydroxocobalamin (Cyanokit, EMD Pharmaceuticals), a newer and potentially safer antidote. The adult dose of hydroxocobalamin is 5 g intravenously (children’s dose is, 70 mg/kg).

DIETARY SUPPLEMENTS & HERBAL PRODUCTS

Following passage of the Dietary Supplement Health and Education Act (DSHEA) in 1994, there has been an increase in the use of dietary supplements and herbal medicines in the United States. Unlike prescription and over-the-counter pharmaceuticals, dietary supplements do not require FDA approval, do not undergo the same pre-marketing evaluation of safety and efficacy as drugs, and purveyors may or may not adhere to good manufacturing practices and quality control standards. Supplements may cause illness as a result of intrinsic toxicity, misidentification or mislabeling, drug-herb reactions, or adulteration with pharmaceuticals. If you suspect a dietary supplement or herbal product may be the cause of an otherwise unexplained illness, contact the FDA (1-888-463-6332) or the regional poison control center (1-800-222-1222), or consult one of the following online databases: http://www.naturaldatabase.therapeuticresearch.com and, http://www.fda.gov/food/dietarysupplements/default.htm.

Table 38–8 lists selected examples of clinical toxicity from some of these products.

DIGITALIS & OTHER CARDIAC GLYCOSIDES

Cardiac glycosides are derived from a variety of plants and are widely used to treat heart failure and supraventricular arrhythmias. These drugs paralyze the \( \text{Na}^+\text{-K}^+\text{-ATPase} \) pump and have potent vagotonic effects. Intracellular effects include enhancement of calcium-dependent contractility and shortening of the action potential duration. A number of plants (eg, oleander, foxglove, lily-of-the-valley)

contain cardiac glycosides. Bufotenin, a cardiotoxic steroid found in certain toad secretions and used as an herbal medicine and a purported aphrodisiac, has pharmacologic properties similar to cardiac glycosides.

Clinical Findings

Intoxication may result from acute single exposure or chronic accidental overmedication. After acute overdosage, nausea and vomiting, bradycardia, hyperkalemia, and AV block frequently occur. Patients in whom toxicity develops gradually during long-term therapy may be hypokalemic and hypomagnesemic owing to concurrent diuretic treatment and more commonly present with ventricular arrhythmias (eg, ectopy, bidirectional ventricular tachycardia, or ventricular fibrillation). Digoxin levels may be only slightly elevated in patients with intoxication from cardiac glycosides other than digoxin because of limited cross-reactivity of immunologic tests.

Treatment

A. Emergency and Supportive Measures

After acute ingestion, administer activated charcoal (see p 1567). Monitor potassium levels and cardiac rhythm closely. Treat bradycardia initially with atropine (0.5–2 mg intravenously) or a transcutaneous external cardiac pacemaker.

B. Specific Treatment

For patients with significant intoxication, administer digoxin-specific antibodies (digoxin immune Fab [ovine]; Digibind or DigiFab). Estimation of the Digibind dose is based on the body burden of digoxin calculated from the ingested dose or the steady-state serum digoxin concentration, as described below. More effective binding of digoxin may be achieved if the dose is given partly as a bolus and the remainder as an infusion over a few hours.

1. From the ingested dose—Number of vials = approximately 1.5–2 × ingested dose (mg).

2. From the serum concentration—Number of vials = serum digoxin (ng/mL) × body weight (kg) × 10–2. Note: This is based on the equilibrium digoxin level; after acute overdose, serum levels may be falsely high before tissue distribution is complete, and overestimation of the Digibind or DigiFab dose is likely.

3. Empiric dosing—Empiric titration of Digibind or DigiFab may be used if the patient’s condition is relatively stable and an underlying condition (eg, atrial fibrillation) favors retaining a residual level of digitalis activity. Start with one or two vials and reassess the patient’s clinical condition after 20–30 minutes. For cardiac glycosides other than digoxin or digitoxin, there is no formula for estimation of vials needed and treatment is entirely based on response to empiric dosing.

Note: After administration of digoxin-specific Fab antibody fragments, serum digoxin levels may be falsely elevated depending on the assay technique.

ETHANOL, BENZODIAZEPINES, & OTHER SEDATIVE-HYPNOTIC AGENTS

The group of agents known as sedative-hypnotic drugs includes a variety of products used for the treatment of anxiety, depression, insomnia, and epilepsy. Besides common benzodiazepines, such as lorazepam, alprazolam, clonazepam, diazepam, oxazepam, chlordiazepoxide, and triazolam, this group includes the newer benzodiazepine-like hypnotics zolpidem and zaleplon, and the muscle relaxant carisoprodol. Ethanol and other selected agents are also popular recreational drugs. All of these drugs depress the central nervous system reticular activating system, cerebral cortex, and cerebellum.

Clinical Findings

Mild intoxication produces euphoria, slurred speech, and ataxia. Ethanol intoxication may produce hypoglycemia, even at relatively low concentrations, in children and in fasting adults. With more severe intoxication, stupor, coma, and respiratory arrest may occur. Carisoprodol (Soma) commonly causes muscle jerking or myoclonus. Death or serious morbidity is usually the result of pulmonary aspiration of gastric contents. Bradycardia, hypotension, and hypothermia are common. Patients with massive intoxication may appear to be dead, with no reflex responses and even absent electroencephalographic activity. Diagnosis and assessment of severity of intoxication are usually based on clinical findings. Ethanol serum levels > 300 mg/dL (0.3 g/dL; 65 mmol/L) can produce coma in persons who are not chronically abusing the drug, but regular users may remain awake at much higher levels.

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal if the patient has ingested a massive dose and the airway is protected (see p 1567). Repeat-dose charcoal may enhance elimination of phenobarbital, but it has not been proved to improve clinical outcome. Hemodialysis may be necessary for patients with severe phenobarbital intoxication.

B. Specific Treatment

Flumazenil is a benzodiazepine receptor-specific antagonist; it has no effect on ethanol, barbiturates, or other sedative-hypnotic agents. If used, flumazenil is given slowly intravenously, 0.2 mg over 30–60 seconds, and repeated in

Bandara V et al. A review of the natural history, toxicology, diagnosis and clinical management of Nerium oleander (common oleander) and Thevetia peruviana (yellow oleander) poisoning. Toxicon. 2010 Sep 1;56(3):273–81. [PMID: 20438745]

0.2-0.5 mg increments as needed up to a total dose of 3–5 mg. Caution: Flumazenil may induce seizures in patients with preexisting seizure disorder, benzodiazepine addiction, or concomitant tricyclic antidepressant or other convulsant overdose. If seizures occur, diazepam and other benzodiazepine anticonvulsants will not be effective. As with naloxone, the duration of action of flumazenil is short (2–3 hours) and re sedation may occur, requiring repeated doses.

γ-HYDROXYBUTYRATE (GHB)

GHB has become a popular drug of abuse. It originated as a short-acting general anesthetic and is occasionally used in the treatment of narcolepsy. It gained popularity among bodybuilders for its alleged growth hormone stimulation and found its way into social settings, where it is consumed as a liquid. It has been used to facilitate sexual assault (“date-rape” drug). Symptoms after ingestion include drowsiness and lethargy followed by coma with respiratory depression. Muscle twitching and seizures are sometimes observed. Recovery is usually rapid, with patients awakening within a few hours. Other related chemicals with similar effects include butanediol and γ-butyrolactone (GBL). A prolonged withdrawal syndrome has been described in some heavy users.

Treatment

Monitor the airway and assist breathing if needed. There is no specific treatment. Most patients recover rapidly with supportive care. GHB withdrawal syndrome may require very large doses of benzodiazepines.

HYPOGLYCEMIC DRUGS

Medications used for diabetes mellitus include insulin, sulfonylureas and other insulin secretagogues, α-glucosidase inhibitors (acarbose, miglitol), biguanides (metformin), thiazolidinediones (pioglitazone, rosiglitazone), and newer peptide analogs (pramlintide, exenatide) or enhancers (sitagliptin) (see Chapter 27). Of these, insulin and the insulin secretagogues are the most likely to cause hypoglycemia. Metformin can cause lactic acidosis, especially in patients with renal insufficiency or after intentional drug overdose. Table 27–7 lists the duration of hypoglycemic effect of oral hypoglycemic agents and Figure 27–3 the extent and duration of various types of insulins.

Clinical Findings

Hypoglycemia may occur quickly after injection of short-acting insulins or may be delayed and prolonged, especially if a large amount has been injected into a single area, creating a “depot” effect. Hypoglycemia after sulfonylurea ingestion is usually apparent within a few hours but may be delayed several hours, especially if food or glucose-containing fluids have been given.

Treatment

Give sugar and carbohydrate-containing food or liquids by mouth, or intravenous dextrose if the patient is unable to swallow safely. For severe hypoglycemia, start with D50W, 50 mL intravenously (25 g dextrose); repeat, if needed. Follow up with dextrose-containing intravenous fluids (D5W or D10W) to maintain a blood glucose > 70–80 mg/dL.

For hypoglycemia caused by sulfonylureas and related insulin secretagogues, consider use of octreotide, a synthetic somatostatin analog that blocks pancreatic insulin release. A dose of 50–100 mcg octreotide subcutaneously every 6–12 hours can reduce the need for exogenous dextrose and prevent rebound hypoglycemia from excessive dextrose dosing.

Admit all patients with symptomatic hypoglycemia after sulfonylurea overdose. Observe asymptomatic overdose patients for at least 12 hours.

IRON

Iron is widely used therapeutically for the treatment of anemia and as a daily supplement in multiple vitamin preparations. Most children’s preparations contain about 12–15 mg of elemental iron (as sulfate, gluconate, or fumarate salt) per dose, compared with 60–90 mg in most adult-strength preparations. Iron is corrosive to the gastrointestinal tract and, once absorbed, has depressant effects on the myocardium and on peripheral vascular resistance. Intracellular toxic effects of iron include disruption of Krebs cycle enzymes.

Clinical Findings

Ingestion of < 30 mg/kg of elemental iron usually produces only mild gastrointestinal upset. Ingestion of > 40–60 mg/kg
may cause vomiting (sometimes with hematemesis), diarrhea, hypotension, and acidosis. Death may occur as a result of profound hypotension due to massive fluid losses and bleeding, metabolic acidosis, peritonitis from intestinal perforation, or sepsis. Fulminant hepatic failure may occur. Survivors of the acute ingestion may suffer permanent gastrointestinal scarring.

Serum iron levels > 350–500 mcg/dl are considered potentially toxic, and levels > 1000 mcg/dl are usually associated with severe poisoning. A plain abdominal radiograph may reveal radiopaque tablets.

**Treatment**

**A. Emergency and Supportive Measures**

Treat hypotension aggressively with intravenous crystalloid solutions (0.9% saline or lactated Ringer solution). Fluid losses may be massive owing to vomiting and diarrhea as well as third-spacing into injured intestine.

Perform whole bowel irrigation to remove unabsorbed pills from the intestinal tract (see p 1567). Activated charcoal is not effective but may be appropriate if other ingesta are suspected.

**B. Specific Treatment**

Deferoxamine is a selective iron chelator. It is not useful as an oral binding agent. For patients with established manifestations of toxicity—and particularly those with markedly elevated serum iron levels (eg, > 800–1000 mcg/dL)—administer 10–15 mg/kg by constant intravenous infusion; higher doses (up to 40–50 mg/kg/h) have been used in massive poisonings. Hypotension may occur. The presence of an iron–deferoxamine complex in the urine may give it a “vin rosé” appearance. Deferoxamine is safe for use in pregnant women with acute iron overdose. Caution: Prolonged infusion of deferoxamine (> 36–48 hours) has been associated with development of acute respiratory distress syndrome (ARDS)—the mechanism is not known.

**Lead**

Lead is used in a variety of industrial and commercial products, such as storage batteries, solders, paints, pottery, plumbing, and gasoline and is found in some traditional Hispanic and Ayurvedic ethnic medicines. Lead toxicity usually results from chronic repeated exposure and is rare after a single ingestion. Lead produces a variety of adverse effects on cellular function and primarily affects the nervous system, gastrointestinal tract, and hematopoietic system.

**Clinical Findings**

Confusion, slurred speech, and seizures may occur abruptly after acute overdose. Severe lactic acidosis—out of proportion to the severity of seizures—is probably due to inhibited metabolism of lactate. Peripheral neuropathy and acute hepatitis may occur with long-term use.

Diagnosis is based on a history of ingestion and the presence of severe acidosis associated with seizures. INH is not usually included in routine toxicologic screening, and serum levels are not readily available.

**Treatment**

**A. Emergency and Supportive Measures**

Seizures may require higher than usual doses of benzodiazepines (eg, lorazepam, 3–5 mg intravenously) or administration of pyridoxine as an antidote (see below).

Administer activated charcoal (see p 1567) after large recent ingestion, but with caution because of the risk of abrupt onset of seizures.

**B. Specific Treatment**

Pyridoxine (vitamin B₆) is a specific antagonist of the acute toxic effects of INH and is usually successful in controlling convulsions that do not respond to benzodiazepines. Give 5 g intravenously over 1–2 minutes or, if the amount ingested is known, give a gram-for-gram equivalent amount of pyridoxine. Patients taking INH are usually given 25–50 mg of pyridoxine orally daily to help prevent neuropathy.

Gokhale YA et al. Isoniazid toxicity presenting as status epilepticus and severe metabolic acidosis. J Assoc Physicians India. 2009 Jan;57:70–1. [PMID: 19753763]

Diagnosis is based on measurement of the blood lead level. Whole blood lead levels < 10 mcg/dL are usually considered nontoxic. Levels between 10 and 25 mcg/dL have been associated with impaired neurobehavioral development in children. Levels of 25–50 mcg/dL may be associated with headache, irritability, and subclinical neuropathy. Levels of 50–70 mcg/dL are associated with moderate toxicity, and levels > 70–100 mcg/dL are often associated with severe poisoning. Other laboratory findings of lead poisoning include microcytic anemia with basophilic stippling and elevated free erythrocyte protoporphyrin.

**Treatment**

**A. Emergency and Supportive Measures**

For patients with encephalopathy, maintain a patent airway and treat coma and convulsions as described at the beginning of this chapter.

For recent acute ingestion, if a large lead-containing object (eg, fishing weight) is still visible in the stomach on abdominal radiograph, whole bowel irrigation (see p 1567), endoscopy, or even surgical removal may be necessary to prevent subacute lead poisoning. (The acidic gastric contents may corrode the metal surface, enhancing lead absorption. Once the object passes into the small intestine, the risk of toxicity declines.)

Conduct an investigation into the source of the lead exposure.

Workers with a single lead level > 60 mcg/dL (or three successive monthly levels > 50 mcg/dL) or construction workers with any single blood lead level > 50 mcg/dL must by federal law be removed from the site of exposure. Contact the regional office of the United States Occupational Safety and Health Administration (OSHA) for more information. Several states mandate reporting of cases of confirmed lead poisoning.

**B. Specific Treatment**

The indications for chelation depend on the blood lead level and the patient’s clinical state. A medical toxicologist or regional poison control center (1-800-222-1222) should be consulted for advice about selection and use of these antidotes.

**Note:** It is impermissible under the law to treat asymptomatic workers with elevated blood lead levels in order to keep their levels < 50 mcg/dL rather than remove them from the exposure.

**1. Severe toxicity**—Patients with severe intoxication (encephalopathy or levels > 70–100 mcg/dL) should receive edetate calcium disodium (ethylenediaminetetraacetic acid, EDTA), 1500 mg/m²/kg/d (approximately 50 mg/kg/d) in four to six divided doses or as a continuous intravenous infusion. Most clinicians also add dimercaprol (BAL), 4–5 mg/kg intramuscularly every 4 hours for 5 days, for patients with encephalopathy.

**2. Less severe toxicity**—Patients with less severe symptoms and asymptomatic patients with blood lead levels between 55 and 69 mcg/dL may be treated with edetate calcium disodium alone in dosages as above. An oral chelator, succimer (DMSA), is available for use in patients with mild to moderate intoxication. The usual dose is 10 mg/kg orally every 8 hours for 5 days, then every 12 hours for 2 weeks.

**LITHIUM**

Lithium is widely used for the treatment of bipolar depression and other psychiatric disorders. The only normal route of lithium elimination is via the kidney, so patients with chronic kidney disease are at risk for accumulation of lithium resulting in gradual onset (chronic) toxicity. Intoxication resulting from chronic accidental overmedication or renal impairment is more common and usually more severe than that seen after acute oral overdose.

**Clinical Findings**

Mild to moderate toxicity causes lethargy, confusion, tremor, ataxia, and slurred speech. This may progress to myoclonic jerking, delirium, coma, and convulsions. Recovery may be slow and incomplete following severe intoxication. Laboratory studies in patients with chronic intoxication often reveal an elevated serum creatinine and an elevated BUN/creatinine ratio due to underlying volume contraction. The white blood cell count is often elevated. ECG findings include T-wave flattening or inversion, and sometimes bradycardia or sinus node arrest. Nephrogenic diabetes insipidus can occur with overdose or with therapeutic doses. Lithium levels may be difficult to interpret. Lithium has a low toxic:therapeutic ratio and chronic intoxication can be seen with levels only slightly above the therapeutic range (0.8–1.2 mEq/L). In contrast, patients with acute ingestion may have transiently very high levels (up to 10 mEq/L reported) without any symptoms before the lithium fully distributes into tissues. **Note:** Falsely high lithium levels (as high as 6–8 mEq/L) can be measured if a green-top blood specimen tube (containing lithium heparin) is used instead of a red- or marbled-top tube.

**Treatment**

After acute oral overdose, consider gastric lavage (see p 1567) or whole bowel irrigation (see p 1567) to prevent systemic absorption (lithium is not adsorbed by activated charcoal). In all patients, evaluate renal function and volume status, and give intravenous saline-containing fluids as needed. Monitor serum lithium levels, and seek assistance with their interpretation and the need for dialysis from a medical toxicologist or regional poison control center (1-800-222-1222). Consider hemodialysis if the patient is markedly symptomatic or if the serum level
A variety of substances—ranging from naturally occurring plants and mushrooms to synthetic substances such as phencyclidine (PCP), tolune and other solvents, dextromethorphan, and lysergic acid diethylamide (LSD)—are abused for their hallucinogenic properties. The mechanism of toxicity and the clinical effects vary for each substance.

Many hallucinogenic plants and mushrooms produce anticholinergic delirium, characterized by flushed skin, dry mucous membranes, dilated pupils, tachycardia, and urinary retention. Other plants and mushrooms may contain hallucinogenic indoles such as mescaline and LSD, which typically cause marked visual hallucinations and perceptual distortion, widely dilated pupils, and mild tachycardia. PCP, a dissociative anesthetic agent similar to ketamine, can produce fluctuating delirium and coma, often associated with vertical and horizontal nystagmus. Toluene and other hydrocarbon solvents (butane, trichloroethylene, "chemo," etc) cause euphoria and delirium and may sensitize the myocardium to the effects of catecholamines, leading to fatal dysrhythmias. Newer drugs used for their psychostimulant effects include synthetic cannabinoid receptor agonists (street names include "spice" and "K2"), Salvia divinorum, and methedrone. See www.erowid.org for very thorough descriptions of a variety of hallucinogenic substances.

### Treatment

#### A. Emergency and Supportive Measures

Maintain a patent airway and assist respirations if necessary. Treat coma, hyperthermia, hypertension, and seizures as outlined at the beginning of this chapter. For recent large ingestions, consider giving activated charcoal orally or by gastric tube (see p 1567).

#### B. Specific Treatment

Patients with anticholinergic delirium may benefit from a dose of physostigmine, 0.5–1 mg intravenously, not to exceed 1 mg/min. Dysphoria, agitation, and psychosis associated with LSD or mescaline intoxication may respond to benzodiazepines (eg, lorazepam, 1–2 mg orally or intravenously) or haloperidol (2–5 mg intramuscularly or intravenously) or another antipsychotic drug (eg, olanzapine or ziprasidone). Monitor patients who have sniffed solvents for cardiac dysrhythmias (most commonly premature ventricular contractions, ventricular tachycardia, ventricular fibrillation); treatment with β-blockers such as propranolol (1–5 mg intravenously) or esmolol (250–500 mcg/kg intravenously, then 50 mcg/kg/min by infusion) may be more effective than lidocaine or amiodarone.

### MERCURY

Acute mercury poisoning usually occurs by ingestion of inorganic mercuric salts or inhalation of metallic mercury vapor. Ingestion of the mercuric salts causes a burning sensation in the throat, discoloration and edema of oral mucous membranes, abdominal pain, vomiting, bloody diarrhea, and shock. Direct nephrotoxicity causes acute kidney injury. Inhalation of high concentrations of metallic mercury vapor may cause acute fulminant chemical pneumonia. Chronic mercury poisoning causes weakness, ataxia, intention tremors, irritability, and depression. Exposure to alkyl (organic) mercury derivatives from highly contaminated fish or fungicides used on seeds has caused ataxia, tremors, convulsions, and catastrophic birth defects. Nearly all fish have some traces of mercury contamination; the US Environmental Protection Agency (EPA) advises consumers to avoid swordfish, shark, king mackerel, and tilefish because they contain higher levels. Fish that are generally low in mercury content include shrimp, canned light tuna (not albacore “white” tuna), salmon, pollock, and catfish. Dental fillings composed of mercury amalgam pose a very small risk of chronic mercury poisoning and their removal is rarely justified.
METHANOL & ETHYLENE GLYCOL

Methanol (wood alcohol) is commonly found in a variety of products, including solvents, duplicating fluids, record cleaning solutions, and paint removers. It is sometimes ingested intentionally by alcoholic patients as a substitute for ethanol and may also be found as a contaminant in bootleg whiskey. Ethylene glycol is the major constituent in most antifreeze compounds. The toxicity of both agents is caused by metabolism to highly toxic organic acids—methanol to formic acid; ethylene glycol to glycolic and oxalic acids. Diethylene glycol is a nephrotoxic solvent that has been improperly substituted for glycerine in various liquid medications (cough syrup, teething medicine, acetaminophen) causing numerous deaths in Haiti, Panama, and Nigeria.

Clinical Findings

Shortly after ingestion of methanol or ethylene glycol, patients usually appear “drunk.” The serum osmolality (measured with the freezing point device) is usually increased, but acidosis is often absent early. After several hours, metabolism to toxic organic acids leads to a severe anion gap metabolic acidosis, tachypnea, confusion, convulsions, and coma. Methanol intoxication frequently causes visual disturbances, while ethylene glycol often produces oxalate crystalluria and acute renal failure.

Treatment

A. Emergency and Supportive Measures

For patients presenting within 30–60 minutes after ingestion, empty the stomach by aspiration through a nasogastric tube (see p 1567). Charcoal is not very effective but should be administered if other poisons or drugs have also been ingested.

B. Specific Treatment

Patients with significant toxicity (manifested by severe metabolic acidosis, altered mental status, and markedly elevated osmol gap) should undergo hemodialysis as soon as possible to remove the parent compound and the toxic metabolites. Treatment with folic acid, thiamine, and pyridoxine may enhance the breakdown of toxic metabolites.

Ethanol blocks metabolism of the parent compounds by competing for the enzyme alcohol dehydrogenase. Fomepizole (4-methylpyrazole; Antizol) blocks alcohol dehydrogenase and is much easier to use than ethanol. If started before onset of acidosis, fomepizole may be used as the sole treatment for ethylene glycol ingestion in some cases. A regional poison control center (1-800-222-1222) should be contacted for indications and dosing.

METHEMOGLOBINEMIA-INDUCING AGENTS

A large number of chemical agents are capable of oxidizing ferrous hemoglobin to its ferric state (methemoglobin), a form that cannot carry oxygen. Drugs and chemicals known to cause methemoglobinemia include benzocaine (a local anesthetic found in some topical anesthetic sprays and a variety of nonprescription products), aniline, propanil (an herbicide), nitrites, nitrogen oxide gases, nitrobenzene, dapsone, phenazopyridine (Pyridium), and many others. Dapsone has a long elimination half-life and may produce prolonged or recurrent methemoglobinemia.

Clinical Findings

Methemoglobinemia reduces oxygen-carrying capacity and may cause dizziness, nausea, headache, dyspnea, confusion, seizures, and coma. The severity of symptoms depends on the percentage of hemoglobin oxidized to methemoglobin; severe poisoning is usually present when methemoglobin fractions are > 40–50%. Even at low levels (15–20%), victims appear cyanotic because of the “chocolate brown” color of methemoglobin, but they have normal P O₂ results on arterial blood gas determinations. Conventional pulse oximetry gives inaccurate oxygen saturation measurements; the reading is often between 85% and 90%. (A newer pulse oximetry device [Masimo Pulse CO-oximeter] is capable of estimating the methemoglobin level.) Severe metabolic acidosis may be present. Hemolysis may occur, especially in patients susceptible to oxidant stress (ie, those with glucose-6-phosphate dehydrogenase deficiency).

Treatment

A. Emergency and Supportive Measures

Administer high-flow oxygen. If the causative agent was recently ingested, administer activated charcoal (see p 1567). Repeat-dose activated charcoal may enhance dapsone elimination (see p 1568).

B. Specific Treatment

Methylene blue enhances the conversion of methemoglobin to hemoglobin by increasing the activity of the enzyme methemoglobin reductase. For symptomatic patients, administer 1–2 mg/kg (0.1–0.2 mL/kg of 1% solution).
intravenously. The dose may be repeated once in 15–20 minutes if necessary. Patients with hereditary methemoglobin reductase deficiency or glucose-6-phosphate dehydrogenase deficiency may not respond to methylene blue treatment. In severe cases where methylene blue is not available or is not effective, exchange blood transfusion may be necessary.

**MONOAMINE OXIDASE INHIBITORS**

Overdoses of MAO inhibitors (isocarboxazid, phenelzine, selegiline, moclobemide) cause ataxia, excitement, hypertension, and tachycardia, followed several hours later by hypotension, convulsions, and hyperthermia.

Ingestion of tyramine-containing foods may cause a severe hypertensive reaction in patients taking MAO inhibitors. Foods containing tyramine include aged cheese and red wines. Hypertensive reactions may also occur with any sympathomimetic drug. Severe or fatal hyperthermia (serotonin syndrome) may occur if patients receiving MAO inhibitors are given meperidine, fluoxetine, paroxetine, fluvoxamine, venlafaxine, tryptophan, dextromethorphan, tramadol, or other serotonin-enhancing drugs. This reaction can also occur with the newer selective MAO inhibitor moclobemide, and the antibiotic linezolid, which has MAO-inhibiting properties. The serotonin syndrome has also been reported in patients taking selective serotonin reuptake inhibitors (SSRIs) in large doses or in combination with other SSRIs, even in the absence of an MAO inhibitor or meperidine. It is characterized by fever, agitation, delirium, diaphoresis, hyperreflexia, and clonus (spontaneous, inducible, or ocular). Hyperthermia can be life-threatening.

**Treatment**

Administer activated charcoal (see p 1567). Treat severe hypertension with nitroprusside, phentolamine, or other rapid-acting vasodilators (see p 1564). Treat hypotension with fluids and positioning, but avoid use of pressor agents if possible. Observe patients for at least 24 hours, since hyperthermic reactions may be delayed. Treat hyperthermia with aggressive cooling; neuromuscular paralysis if possible. Observe patients for at least 24 hours, since the serotonin syndrome may be delayed. After the onset of symptoms, efforts to remove the toxic agent are probably useless, especially in cases of amatoxin or gyromitrin poisoning, where there is usually a delay of 12 hours or more before symptoms occur and patients seek medical attention. However, induction of vomiting or administration of activated charcoal is recommended for any recent ingestion of an unidentified or potentially toxic mushroom (see p 1567).

**Clinical Findings (Table 38–9)**

A. Symptoms and Signs

Amatoxin-containing mushrooms typically cause a delayed onset (8–12 hours after ingestion) of severe abdominal cramps, vomiting and profuse diarrhea, followed by hepatic necrosis, hepatic encephalopathy, and frequently acute kidney injury in 1–2 days. Cooking the mushrooms does not prevent poisoning. Monomethylhydrazine poisoning (Gyromitra and Helvella species) is more common following ingestion of uncooked mushrooms, as the toxin is water-soluble. Vomiting, diarrhea, hepatic necrosis, convulsions, coma, and hemolysis may occur after a latent period of 8–12 hours. The clinical effects of these and other mushrooms are described in Table 38–9.

**Treatment**

A. Emergency Measures

After the onset of symptoms, efforts to remove the toxic agent are probably useless, especially in cases of amatoxin or gyromitrin poisoning, where there is usually a delay of 12 hours or more before symptoms occur and patients seek medical attention. However, induction of vomiting or administration of activated charcoal is recommended for any recent ingestion of an unidentified or potentially toxic mushroom (see p 1567).

B. Specific Treatment

A variety of purported antidotes (eg, thiocetic acid, penicillin, corticosteroids) have been suggested for amatoxin-type mushroom poisoning, but controlled studies are lacking and experimental data in animals are equivocal. Aggressive fluid replacement for diarrhea and intensive supportive care for hepatic failure are the mainstays of treatment. Silymarin (silibinin), a derivative of milk thistle, is commonly used in Europe but is currently only commercially available in the United States as a nutritional supplement given orally. The European intravenous product (Legalon-SIL) can be obtained in the United States under an emergency IND provided by the FDA. Contact the regional poison control center (1-800-222-1222) for more information.

 Interruption of enterohepatic circulation of the amatoxin by the administration of activated charcoal or by cannulation and drainage of the bile duct may be of value.
in removing some of the toxin, based on animal studies and isolated case reports.

Liver transplant may be the only hope for survival in gravely ill patients—contact a liver transplant center early.

**OPIATES & OPIOIDS**

Prescription and illicit opiates and opioids (morphine, heroin, codeine, oxycodone, fentanyl, hydromorphone, etc) are popular drugs of misuse and abuse and the cause of frequent hospitalizations for overdose. These drugs have widely varying potencies and durations of action; for example, some of the illicit fentanyl derivatives are up to 2000 times more potent than morphine. All of these agents decrease central nervous system activity and sympathetic outflow by acting on opioid receptors in the brain. Tramadol is an analgesic that is unrelated chemically to the opioids but acts on opioid receptors. Buprenorphine is a partial agonist-antagonist opioid used for the outpatient treatment of opioid addiction.

### Treatment

**A. Emergency and Supportive Measures**

Protect the airway and assist ventilation. Administer activated charcoal (see p 1567) for recent large ingestions.

**B. Specific Treatment**

Naloxone is a specific opioid antagonist that can rapidly reverse signs of narcotic intoxication. Although it is structurally related to the opioids, it has no agonist effects of its own. Administer 0.2–2 mg intravenously, and repeat as needed to awaken the patient and maintain airway protective

**Clinical Findings**

Mild intoxication is characterized by euphoria, drowsiness, and constricted pupils. More severe intoxication may cause hypotension, bradycardia, hyperthermia, coma, and respiratory arrest. Pulmonary edema may occur. Death is usually due to apnea or pulmonary aspiration of gastric contents. Methadone has been associated with QT interval prolongation and torsades de pointes. Tramadol, dextromethorphan, and meperidine also occasionally cause seizures. With meperidine, the metabolite normeperidine is probably the cause of seizures and is most likely to accumulate with repeated dosing in patients with chronic kidney disease. While the duration of effect for heroin is usually 3–5 hours, methadone intoxication may last for 48–72 hours or longer. Propoxyphene may cause seizures and prolongs the QRS interval; it has now been removed from the US market by the FDA. Many opioids, including fentanyl, tramadol, oxycodone, and methadone, are not detected on routine urine toxicology "opiate" screening.
reflexes and spontaneous breathing. Very large doses (10–20 mg) may be required for patients intoxicated by some opioids (eg, codeine, fentanyl derivatives). Caution: The duration of effect of naloxone is only about 2–3 hours; repeated doses may be necessary for patients intoxicated by long-acting drugs such as methadone. Continuous observation for at least 3 hours after the last naloxone dose is mandatory.

PESTICIDES: CHOLINESTERASE INHIBITORS

Organophosphorus and carbamate insecticides (organophosphates: parathion, malathion, etc; carbamates: carbaryl, aldicarb, etc) are widely used in commercial agriculture and home gardening and have largely replaced older, more environmentally persistent organochlorine compounds such as DDT and chlordane. The organophosphates and carbamates—also called anticholinesterases because they inhibit the enzyme acetylcholinesterase—cause an increase in acetylcholine activity at nicotinic and muscarinic receptors and in the central nervous system. There are a variety of chemical agents in this group, with widely varying potencies. Most of them are poorly water-soluble, are often formulated with an aromatic hydrocarbon solvent such as xylene, and are well absorbed through intact skin. Most chemical warfare “nerve agents” (such as GA [tabun], GB [sarin], GD [soman] and VX) are organophosphates.

Clinical Findings

Inhibition of cholinesterase results in abdominal cramps, diarrhea, vomiting, excessive salivation, sweating, lacrimation, miosis (constricted pupils), wheezing and bronchorrhea, seizures, and skeletal muscle weakness. Initial tachycardia is usually followed by bradycardia. Profound skeletal muscle weakness, aggravated by excessive bronchial secretions and wheezing, may result in respiratory arrest and death. Symptoms and signs of poisoning may persist or recur over several days, especially with highly lipid-soluble agents such as fenthion or dimethoate.

The diagnosis should be suspected in patients who present with miosis, sweating, and hyperperistalsis. Serum and red blood cell cholinesterase activity is usually depressed at least 50% below baseline in those victims who have severe intoxication.

Treatment

A. Emergency and Supportive Measures

If the agent was recently ingested, consider gut decontamination by aspiration of the liquid using a nasogastric tube followed by administration of activated charcoal (see p 1567). If the agent is on the victim’s skin or hair, wash repeatedly with soap or shampoo and water. Providers should take care to avoid skin exposure by wearing gloves and waterproof aprons. Dilute hypochlorite solution (eg, household bleach diluted 1:10) is reported to help break down organophosphate pesticides and nerve agents on equipment or clothing.

B. Specific Treatment

Atropine reverses excessive muscarinic stimulation and is effective for treatment of salivation, bronchial hypersecretion, wheezing, abdominal cramping, and sweating. However, it does not interact with nicotinic receptors at autonomic ganglia and at the neuromuscular junction and has no direct effect on muscle weakness. Administer 2 mg intravenously, and if there is no response after 5 minutes, give repeated boluses in rapidly escalating doses (eg, doubling the dose each time) as needed to dry bronchial secretions and decrease wheezing; as much as several hundred milligrams of atropine has been given to treat severe poisoning.

Pralidoxime (2-PAM, Protopam) is a specific antidote that reverses organophosphate binding to the cholinesterase enzyme; therefore, it should be effective at the neuromuscular junction as well as other nicotinic and muscarinic sites. It is most likely to be clinically effective if started very soon after poisoning, to prevent permanent binding of the organophosphate to cholinesterase. However, clinical studies have yielded conflicting results regarding the effectiveness of pralidoxime in reducing mortality. Administer 1–2 g intravenously as a loading dose, and begin a continuous infusion (200–500 mg/h, titrated to clinical response). Continue to give pralidoxime as long as there is any evidence of acetylcholine excess. Pralidoxime is of questionable benefit for carbamate poisoning, because carbamates have only a transitory effect on the cholinesterase enzyme. Other, unproven therapies for organophosphate poisoning include magnesium, sodium bicarbonate, clonidine, and extracorporeal removal.

PETROLEUM DISTILLATES & SOLVENTS

Petroleum distillate toxicity may occur from inhalation of the vapor or as a result of pulmonary aspiration of the liquid during or after ingestion. Acute manifestations of aspiration pneumonitis are vomiting, coughing, and bronchopneumonia. Some hydrocarbons—ie, those with aromatic or halogenated subunits—can also cause severe systemic poisoning after oral ingestion. Hydrocarbons can also cause systemic intoxication by inhalation. Vertigo,
muscular incoordination, irregular pulse, myoclonus, and seizures occur with serious poisoning and may be due to hypoxemia or the systemic effects of the agents. Chlorinated and fluorinated hydrocarbons (trichloroethylene, Freons, etc) and many other hydrocarbons can cause ventricular arrhythmias due to increased sensitivity of the myocardium to the effects of endogenous catecholamines.

**Treatment**

Remove the patient to fresh air. For simple aliphatic hydrocarbon ingestion, gastric emptying and activated charcoal are not recommended, but these procedures may be indicated if the preparation contains toxic solutes (eg, an insecticide) or is an aromatic or halogenated product. Observe the victim for 6–8 hours for signs of aspiration pneumonitis (cough, localized crinkles or rhonchi, tachypnea, and infiltrates on chest radiograph). Corticosteroids are not recommended. If fever occurs, give a specific antibiotic only after identification of bacterial pathogens by laboratory studies. Because of the risk of arrhythmias, use bronchodilators with caution in patients with chlorinated or fluorinated solvent intoxication. If tachyarrhythmias occur, use esmolol intravenously 25–100 mcg/kg/min.

**Clinical Findings**

Acute ingestion often causes nausea and vomiting, occasionally with gastritis. Moderate intoxication is characterized by hyperpnea (deep and rapid breathing), tachycardia, tinnitus, and elevated anion gap metabolic acidosis. Serious intoxication may result in agitation, confusion, coma, seizures, cardiovascular collapse, pulmonary edema, hyperthermia, and death. The prothrombin time is often elevated owing to salicylate-induced hypoprothrombinemia. Central nervous system intracellular glucose depletion can occur despite normal measured serum glucose levels.

Diagnosis of salicylate poisoning is suspected in any patient with metabolic acidosis and is confirmed by measuring the serum salicylate level. Patients with levels > 100 mg/dL (1000 mg/L or 7.2 mcmol/L) after an acute overdose are more likely to have severe poisoning. On the other hand, patients with subacute or chronic intoxication may suffer severe symptoms with levels of only 60–70 mg/dL (> 100 hours). Poisoning may also occur as a result of chronic excessive dosing over several days. Although the half-life of salicylate is 2–3 hours after small doses, it may increase to 20 hours or more in patients with intoxication.

**Treatment**

**A. Emergency and Supportive Measures**

Administer activated charcoal orally (see p 1567). Gastric lavage followed by administration of extra doses of activated charcoal may be needed in patients who ingest more than 10 g of aspirin (see p 1567). The desired ratio of charcoal to aspirin is about 10:1 by weight; while this cannot always be given as a single dose, it may be administered over the first 24 hours in divided doses every 2–4 hours along with whole bowel irrigation (see p 1567). Give glucose-containing fluids to reduce the risk of cerebral hypoglycemia. Treat metabolic acidosis with intravenous sodium bicarbonate. This is critical because acidosis (especially acidemia, pH < 7.40) promotes greater entry of salicylate into cells, worsening toxicity. **Warning:** Sudden and severe deterioration can occur after rapid sequence intubation and controlled ventilation if the pH is allowed to fall during the apneic period.
B. Specific Treatment

Alkalization of the urine enhances renal salicylate excretion by trapping the salicylate anion in the urine. Add 100 mEq (two ampules) of sodium bicarbonate to 1 L of 5% dextrose in 0.2% saline, and infuse this solution intravenously at a rate of about 150–200 mL/h. Unless the patient is oliguric or hyperkalemic, add 20–30 mEq of potassium chloride to each liter of intravenous fluid. Patients who are volume-depleted fail to produce an alkaline urine (paradoxical aciduria) unless potassium is given.

Hemodialysis may be lifesaving and is indicated for patients with severe metabolic acidosis, markedly altered mental status, or significantly elevated salicylate levels (eg, > 100–120 mg/dL [1000–1200 mg/L or 7.2–8.6 mcmol/L] after acute overdose or > 60–70 mg/dL [600–700 mg/L or 4.3–5 mcmol/L] with subacute or chronic intoxication).

### Treatment

A. Emergency and Supportive Measures

Caution: Abrupt respiratory arrest may occur in patients with acute paralytic shellfish and puffer fish poisoning. Observe patients for at least 4–6 hours. Replace fluid and electrolyte losses from gastroenteritis with intravenous saline or other crystalloid solution.

For recent ingestions, it may be possible to adsorb residual toxin in the gut with activated charcoal, 50–60 g orally (see p 1567).

B. Specific Treatment

There is no specific antidote for paralytic shellfish or puffer fish poisoning.

1. **Ciguatera**—There are anecdotal reports of successful treatment of acute neurologic symptoms with mannitol, 1 g/kg intravenously, but this approach is not widely accepted.

2. **Scombroid**—Antihistamines such as diphenhydramine, 25–50 mg intravenously, and the H₂-blocker cimetidine, 300 mg intravenously, are usually effective. For severe reactions, give also epinephrine, 0.3–0.5 mL of a 1:1000 solution subcutaneously.

### Table 38–10. Common seafood poisonings.

<table>
<thead>
<tr>
<th>Type of Poisoning</th>
<th>Mechanism</th>
<th>Clinical Presentation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Ciguatera</td>
<td>Reef fish ingest toxic dinoflagellates, whose toxins accumulate in fish meat. Commonly implicated fish in the United States are barracuda, jack, snapper, and grouper.</td>
<td>1–6 hours after ingestion, victims develop abdominal pain, vomiting, and diarrhea accompanied by a variety of neurologic symptoms, including paresthesias, reversal of hot and cold sensation, vertigo, headache, and intense itching. Autonomic disturbances, including hypotension and bradycardia, may occur.</td>
</tr>
<tr>
<td>Scombroid</td>
<td>Improper preservation of large fish results in bacterial degradation of histidine to histamine. Commonly implicated fish include tuna, mahimahi, bonita, mackerel, and kingfish.</td>
<td>Allergic-like (anaphylactoid) symptoms are due to histamine, usually begin within 15–90 minutes, and include skin flushing, itching, urticaria, angioedema, bronchospasm, and hypotension as well as abdominal pain, vomiting, and diarrhea.</td>
</tr>
<tr>
<td>Paralytic shellfish poisoning</td>
<td>Dinoflagellates produce saxitoxin, which is concentrated by filter-feeding mussels and clams. Saxitoxin blocks sodium conductance and neuronal transmission in skeletal muscles.</td>
<td>Onset is usually within 30–60 minutes. Initial symptoms include perioral and intraoral paresthesias. Other symptoms include nausea and vomiting, headache, dizziness, dysphagia, dysarthria, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest.</td>
</tr>
<tr>
<td>Puffer fish poisoning</td>
<td>Tetrodotoxin is concentrated in liver, gonads, intestine, and skin. Toxic effects are similar to those of saxitoxin. Tetrodotoxin is also found in some North American newts and Central American frogs.</td>
<td>Onset is usually within 30–40 minutes but may be as short as 10 minutes. Initial perioral paresthesias are followed by headache, diaphoresis, nausea, vomiting, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest.</td>
</tr>
</tbody>
</table>

### SEAFOOD POISONINGS

A variety of intoxications may occur after eating certain types of fish or other seafood. These include scombroid, ciguatera, paralytic shellfish, and puffer fish poisoning. The mechanisms of toxicity and clinical presentations are described in Table 38–10. In the majority of cases, the seafood has a normal appearance and taste (scombroid may have a peppery taste).
cause respiratory paralysis; cytolytic venoms cause tissue destruction by digestion and hemorrhage due to hemolysis and destruction of the endothelial lining of the blood vessels. The manifestations of rattlesnake envenomation are mostly local pain, redness, swelling, and extravasation of blood. Perioral tingling, metallic taste, nausea and vomiting, hypotension, and coagulopathy may also occur. Thrombocytopenia can persist for several days after a rattlesnake bite. Neurotoxic envenomation may cause ptosis, dysphagia, diplopia, and respiratory arrest.

## Treatment

### A. Emergency Measures

Immobilize the patient and the bitten part in a neutral position. Avoid manipulation of the bitten area. Transport the patient to a medical facility for definitive treatment. Do not give alcoholic beverages or stimulants; do not apply ice; do not apply a tourniquet. The potential trauma to underlying tissues resulting from incision and suction performed by unskilled people is probably not justified in view of the small amount of venom that can be recovered.

### B. Specific Antidote and General Measures

1. **Pit viper (eg, rattlesnake) envenomation**—For local signs such as swelling, pain, and ecchymosis but no systemic symptoms, give 4–6 vials of crotalid antivenin (CroFab) by slow intravenous drip in 250–500 mL saline. Repeated doses of 2 vials every 6 hours for up to 18 hours has been recommended. For more serious envenomation with marked local effects and systemic toxicity (eg, hypotension, coagulopathy), higher doses and additional vials may be required. Monitor vital signs and the blood coagulation profile. Type and cross-match blood. The adequacy of venom neutralization is indicated by improvement in symptoms and signs, and the rate that swelling slows. Prophylactic antibiotics are not indicated after a rattlesnake bite.

2. **Elapid (coral snake) envenomation**—Give 1–2 vials of specific antivenom as soon as possible. To locate antiserum for exotic snakes, call a regional poison control center (1-800-222-1222).

### C. Scorpion Stings

No specific treatment other than analgesics is required for envenomations by most scorpions found in the United States. For *Centruroides* stings, a specific antivenom developed in Arizona was proved effective and was granted FDA approval in 2011.

- Bawaskar HS et al. Efficacy and safety of scorpion antivenom plus prazosin compared with prazosin alone for venomous scorpion (Mesobuthus tianshanensis) sting: randomised open label clinical trial. BMJ. 2011 Jan 5;342:c7136. [PMID: 21209062]

### THEOPHYLLINE & CAFFEINE

Theophylline may cause intoxication after an acute single overdose, or intoxication may occur as a result of chronic overdosage. Visit the work on toxicity from scorpion stings. N Engl J Med. 2009 May 14; 360(20):2090–8. [PMID: 19439743]
accidental repeated overmedication or reduced elimination resulting from hepatic dysfunction or interacting drug (eg, cimetidine, erythromycin). The usual serum half-life of theophylline is 4–6 hours, but this may increase to more than 20 hours after overdose. Caffeine and caffeine-containing herbal products can produce similar toxicity.

Clinical Findings
Mild intoxication causes nausea, vomiting, tachycardia, and tremulousness. Severe intoxication is characterized by ventricular and supraventricular tachyarrhythmias, hypotension, and seizures. Status epilepticus is common and often intractable to the usual anticonvulsants. After acute overdose (but not chronic intoxication), hypokalemia, hyperglycemia, and metabolic acidosis are common. Seizures and other manifestations of toxicity may be delayed for several hours after acute ingestion, especially if a sustained-release preparation such as Theo-Dur was taken.

Diagnosis is based on measurement of the serum theophylline concentration. Seizures and hypotension are likely to develop in acute overdose patients with serum levels > 100 mg/L (555 mc mole/L). Serious toxicity may develop at lower levels (ie, 40–60 mg/L [222–333 mc mole/L]) in patients with chronic intoxication.

Treatment
A. Emergency and Supportive Measures
After acute ingestion, administer activated charcoal (see p 1567). Repeated doses of activated charcoal may enhance theophylline elimination by “gut dialysis.” Addition of whole bowel irrigation should be considered for large ingestions involving sustained-release preparations (see p 1567).

Hemodialysis is effective in removing theophylline and is indicated for patients with status epilepticus or markedly elevated serum theophylline levels (eg, > 100 mg/L [555 mc mole/L] after acute overdose or > 60 mg/L [333 mc mole/L] with chronic intoxication).

B. Specific Treatment
Treat seizures with benzodiazepines (lorazepam, 2–3 mg intravenously, or diazepam, 5–10 mg intravenously) or phenobarbital (10–15 mg/kg intravenously). Phenytoin is not effective. Hypotension and tachycardia—which are mediated through excessive β-adrenergic stimulation—may respond to β-blocker therapy even in low doses. Administer esmolol, 25–50 mcg/kg/min by intravenous infusion, or propranolol, 0.5–1 mg intravenously.

TRICYCLIC & OTHER ANTIDEPRESSANTS
Tricyclic and related cyclic antidepressants are among the most dangerous drugs involved in suicidal overdose. These drugs have anticholinergic and cardiac depressant properties (“quinidine-like” sodium channel blockade). Tricyclic antidepressants produce more marked membrane-depressant cardiotoxic effects than the phenothiazines.

Newer antidepressants such as trazodone, fluoxetine, citalopram, paroxetine, sertraline, bupropion, venlafaxine, and fluvoxamine are not chemically related to the tricyclic antidepressant agents and do not generally produce quinidine-like cardiotoxic effects. However, they may cause seizures in overdoses and they may cause serotonin syndrome (see Monoamine Oxidase Inhibitors section).

Clinical Findings
Signs of severe intoxication may occur abruptly and without warning within 30–60 minutes after acute tricyclic overdose. Anticholinergic effects include dilated pupils, tachycardia, dry mouth, flushed skin, muscle twitching, and decreased peristalsis. Quinidine-like cardiotoxic effects include QRS interval widening (> 0.12 s; Figure 38–2), ventricular arrhythmias, AV block, and hypotension. Rightward-axis deviation of the terminal 40 ms of the QRS has also been described. Prolongation of the QT interval and torsades de pointes have been reported with several of the newer antidepressants. Seizures and coma are common with severe intoxication. Life-threatening hyperthermia may result from status epilepticus and anticholinergic-induced impairment of sweating. Among newer agents, bupropion and venlafaxine have been associated with a greater risk of seizures.

The diagnosis should be suspected in any overdose patient with anticholinergic side effects, especially if there is widening of the QRS interval or seizures. For
intoxication by most tricyclic antidepressants, the QRS interval correlates with the severity of intoxication more reliably than the serum drug level.

Serotonin syndrome should be suspected if agitation, delirium, diaphoresis, tremor, hyperreflexia, clonus (spontaneous, inducible, or ocular), and fever develop in a patient taking serotonin reuptake inhibitors.

**Treatment**

**A. Emergency and Supportive Measures**

Observe patients for at least 6 hours, and admit all patients with evidence of anticholinergic effects (eg, delirium, dilated pupils, tachycardia) or signs of cardiotoxicity (see above).

Administer activated charcoal (see p 1567) and consider gastric lavage (see p 1567) after recent large ingestions. All of these drugs are highly tissue-bound and are not effectively removed by hemodialysis procedures.

**B. Specific Treatment**

Cardioxic sodium channel-depressant effects of tricyclic antidepressants may respond to boluses of sodium bicarbonate (50–100 mEq intravenously). Sodium bicarbonate provides a large sodium load that alleviates depression of the sodium-dependent channel. Reversal of acidosis may also have beneficial effects at this site. Maintain the pH between 7.45 and 7.50. Alkalization does not promote excretion of tricyclic antidepressants. Prolongation of the QT interval or torsades de pointes is usually treated with intravenous magnesium or overdrive pacing. Severe cardiotoxicity in patients with overdoses of lipid-soluble drugs (eg, amitriptyline, bupropion) has responded to intravenous lipid emulsion (Intralipid).

Mild serotonin syndrome may be treated with benzodiazepines and withdrawal of the antidepressant. Moderate cases may respond to cyproheptadine (4 mg orally or via gastric tube hourly for three or four doses) or chlorpromazine (25 mg intravenously). Severe hyperthermia should be treated with neuromuscular paralysis and endotracheal intubation in addition to external cooling measures.

---

The major features of this chapter are the clinical aspects of cancer, including etiology and prevention; staging; diagnosis and treatment of common cancers; and recognition and management of complications from cancer. Additional information may be obtained from the National Cancer Institute (NCI) website at www.cancer.gov/cancer topics, the American Society of Clinical Oncology website at www.asco.org, and the National Comprehensive Cancer Network (NCCN) website at www.nccn.org. The NCCN website provides detailed, evidence-based recommendations for management of specific cancers as well as guidelines for cancer screening and for supportive care. General reviews in oncology can be obtained from Medscape Hematology/Oncology (www.medscape.com).

**Etiology**

Cancer is the second most common cause of death in the United States. In 2011 an estimated 1,596,670 cases of cancer were diagnosed, and 571,950 persons died as a result of cancer. Based on cancer rates determined in 2003–2005, more than 40% of people born today will have cancer diagnosed at some point in their lifetime. Table 39–1 lists the 10 leading cancer types in men and women by site.

However, the incidence of cancer in both men and women is decreasing. In 2008, the American Cancer Society, NCI, and the Centers for Disease Control and Prevention reported that the incidence of all cancers for both sexes decreased 0.8% per year from 1999 through 2005. As the incidence of cancer is decreasing, the survival rate is increasing. In 2010, using information from the Surveillance Epidemiology and End Results (SEER) database, the NCI reported a survival rate of 68% for individuals in whom cancer was diagnosed between 1999 and 2006 compared to 50% for those in whom cancer was diagnosed between 1975 and 1977.

Reductions in cancer incidence and mortality reflect a successful implementation of a broad strategy of prevention, detection, and treatment.

**Modifiable Risk Factors**

Tobacco is the most common preventable cause of cancer death; it is estimated that at least 30% of all cancer deaths in the United States are directly linked to tobacco. A total of 171,000 cancer deaths in the United States and 1.42 million cancer deaths worldwide can be directly attributed to tobacco abuse. Clear evidence links at least 15 cancers to tobacco use. The most dramatic link is with lung cancer, the most common non-dermatologic malignancy; 87% of lung cancer cases occur in smokers. Any strategy for cancer control must include the goal of markedly reducing if not eliminating tobacco use.

Strategies for tobacco control should involve a focus on the individual as well as society as a whole. Tobacco cessation directed toward the individual should start with the clinician providing counseling. Simple, concise advice from a clinician can yield cessation rates of 10–20%. Additive strategies include more intensive counseling; nicotine replacement therapy with patches, gum, or lozenges; and prescription medication with bupropion or varenicline. Perhaps a more intriguing phenomenon, with potential for significant impact on cessation rates, is the influence of social contact behavior on an individual smoker’s abstinence decision. For instance, analysis of the Framingham Heart Study demonstrated that smoking cessation by a spouse resulted in a 67% decrease in the subject’s likelihood of continuing to smoke, and smoking cessation by a friend resulted in a 36% decrease in the subject’s likelihood of smoking.

On a societal level, many initiatives have been put into place to actively discourage tobacco use. State or local laws regulating tobacco use in restaurants, the workplace, and other public places have resulted in declines in tobacco use. Countermarketing with aggressive anti-tobacco advertisements has also contributed to tobacco cessation and abstinence. The key recipients of these messages are children; 80% of smokers will start by age 18. Preventing the start of addiction in this vulnerable population should be a top priority (see Chapter 1).

There are encouraging signs of success with tobacco control. The prevalence of smoking for United States adults based on the 2011 National Health Interview Survey is 19.4%, which is a remarkable reduction from the 1955 peak of 57% for males and the 1965 peak of 34% for females but still falls short of the Healthy People 2010 goal of < 12%. See Chapter 1 for additional material on smoking cessation techniques.
Cancers are established and published by the American Joint Committee on Cancer (AJCC). Elements used for staging include tumor location, size and level of tumor invasion (T), absence or presence and extent of nodal metastases (N), and presence or absence of systemic metastases (M). Once the TNM designations have been determined, an overall stage is assigned, stage I, II, III, or IV. Clinical staging utilizes physical examination, laboratory and imaging tests as well as results from biopsies; pathologic staging relies on the results from surgery. In some instances, other classifications may be used for certain cancers such as the Ann Arbor staging system for lymphomas.

Other characteristics of cancers, not reflected in the TNM stage, may be used as another indicator of prognosis. Pathologic features seen on routine histologic examination for some cancers are very important; examples include the Gleason score for prostate cancer and the grade of sarcomas. Cancer specimens may also be sent for targeted molecular diagnostic testing; results are used to determine prognosis as well as treatment. Examples include testing for HER-2/neu in breast and gastric cancers, KRAS and BRF mutations in colorectal cancers, and EGFR and KRAS mutations in lung cancer. In the future, as the pathways for oncogenesis and relationships of mutations to treatment and prognosis are better delineated, analysis for detection of chromosomal alterations and oncogene products will continue to be increasingly incorporated into routine practice.

### THE PARANEOPLASTIC SYNDROMES

The clinical manifestations of cancer are usually due to pressure effects of local tumor growth, infiltration or metastatic deposition of tumor cells in a variety of organs in the body, or certain systemic symptoms. General problems observed in many patients with advanced or widespread metastatic cancer include anorexia, malaise, weight loss, and sometimes fever. These characteristics must be considered when evaluating a patient with an undiagnosed illness. Except in the case of functioning tumors such as those of the endocrine glands, systemic symptoms of cancer usually are not specific, often consisting of weakness, anorexia, and weight loss. The term “paraneoplastic” refers to features of disease considered to be due to the remote effects of a cancer. These features cannot be attributed either to a cancer’s direct invasive or metastatic properties and are often considered to be due to aberrant hormonal or metabolic effects not observed in a cancer’s normal tissue equivalent. In the paraneoplastic syndromes, clinical findings may resemble those of primary endocrine, metabolic, hematologic, or neuromuscular disorders. At present, the mechanisms for such remote effects can be classified into three groups: (1) effects initiated by a tumor product (eg, carcinoen without the need to integrate images or diagrams.
secreted by the more differentiated normal endocrine cell. Such ectopic hormone production by cancer cells is believed to result from activation of genes in the malignant cells that are suppressed in the normal tissue equivalent and in most somatic cells. Autocrine growth factors secreted by neoplastic cells may also result in paraneoplastic syndromes. Small cell lung cancer is the one type of cancer most likely to be associated with paraneoplastic syndromes.

The paraneoplastic syndromes are clinically important for the following reasons:

1. They sometimes accompany relatively limited neoplastic growth and may provide the clinician with an early clue to the presence of certain types of cancer.
2. The metabolic or toxic effects of the syndrome may constitute a more urgent hazard to the patient’s life than the underlying cancer (eg, hypercalcemia, hyponatremia).
3. Effective treatment of the tumor should be accompanied by resolution of the paraneoplastic syndrome and, conversely, recurrence of the cancer may be heralded by return of the systemic symptoms. In some instances, rapid response to cytotoxic chemotherapy may briefly increase the severity of the paraneoplastic syndrome in association with tumor lysis (eg, hyponatremia with inappropriate antidiuretic hormone excretion). In some instances the identical symptom complex (eg, hypercalcemia) may be induced by entirely different mechanisms. A single syndrome such as hypercalcemia may be due to any one of a variety of humoral factors, such as secretion of parathyroid hormone precursors or homologs or 1,25 dihydroxyvitamin D. Effective antitumor treatment usually results in return of serum calcium to normal.

Common paraneoplastic syndromes and endocrine secretions associated with functional cancers are summarized in Table 39–2.

### LUNG CANCER

Sunny Wang, MD

#### BRONCHOGENIC CARCINOMA

#### ESSENTIALS OF DIAGNOSIS

- New cough, or change in chronic cough.
- Dyspnea, hemoptysis, anorexia, weight loss.
- Enlarging nodule or mass; persistent opacity, atelectasis, or pleural effusion on chest radiograph or CT scan.
- Cytologic or histologic findings of lung cancer in sputum, pleural fluid, or biopsy specimen.

#### General Considerations

Lung cancer is the leading cause of cancer deaths in both men and women. The American Cancer Society estimates 226,160 new diagnoses and 160,340 deaths from lung cancer in the United States in 2012, accounting for approximately 14% of new cancer diagnoses and 28% of all cancer deaths. More Americans die of lung cancer than of colorectal, breast, and prostate cancers combined.

Cigarette smoking causes 85–90% of cases of lung cancer. Lung cancer was a previously reportable disease until the widespread use of manufactured cigarettes in the 20th century. The causal connection between cigarettes and lung cancer is established not only epidemiologically but also through identification of carcinogens in tobacco smoke and analysis of the effect of these carcinogens on specific oncogenes expressed in lung cancer.

Since the early 1990s, mortality from lung cancer fell among men while it increased among women and is only now peaking among women, reflecting changing patterns of tobacco use over the past 30 years (see Chapter 1). Other environmental risk factors for the development of lung cancer include exposure to environmental tobacco smoke, radon gas (among uranium miners and in areas where radium in the soil causes significant indoor air contamination), asbestos (60- to 100-fold increased risk in smokers with asbestos exposure), metals (arsenic, chromium, nickel, iron oxide), and industrial carcinogens (bis-chloromethyl ether). A familial predisposition to lung cancer is recognized. Certain diseases are associated with an increased risk of lung cancer, including pulmonary fibrosis, chronic obstructive pulmonary disease, and sarcoïdosis. Second primary lung cancers are more frequent in patients who survive their initial lung cancer.

The median age at diagnosis of lung cancer in the United States is 71; it is unusual under the age of 40. After the diagnosis of lung cancer is made, approximately 41% of patients survive 1 year. The combined relative 5-year survival rate for all stages of lung cancer is currently 16%, slightly improved from 13% for lung cancers diagnosed in the 1970-80s.

Five histologic categories of bronchogenic carcinoma account for more than 90% of cases of primary lung cancer. Squamous cell carcinoma (20% of cases) arises from the bronchial epithelium, typically as a centrally located, intraluminal sessile or polypoid mass. Squamous cell tumors are more likely to present with hemoptysis and more frequently diagnosed by sputum cytology. They spread locally and may be associated with hilar adenopathy and mediastinal widening on chest radiography. Adenocarcinoma (35–40% of cases) arises from mucus glands or, in the case of bronchioloalveolar cell carcinoma (2% of cases), from any epithelial cell within or distal to the terminal bronchioles. Adenocarcinomas usually present as peripheral nodules or masses. Bronchioloalveolar cell carcinoma, now known as adenocarcinoma in situ, spreads along preexisting alveolar structures (lepidic growth) without evidence of invasion. Large cell carcinoma (3–5% of cases) is a heterogeneous group of relatively undifferentiated tumors that share large cells and do not fit into other categories. Large cell carcinomas typically have rapid doubling times and an aggressive clinical course. They present as central or peripheral masses. Tumors that are not better differentiated on pathologic review other than carcinoma...

+, reported associated; ++, strong association.
SIADH, syndrome of inappropriate antidiuretic hormone.
unspecified make up about 20–25% of cases. Small cell carcinoma (10–15% of cases) is a tumor of bronchial origin that typically begins centrally, infiltrating submucosally to cause narrowing or obstruction of the bronchus without a discrete luminal mass. Hilary and mediastinal abnormalities are common on chest radiography.

For purposes of staging and treatment, bronchogenic carcinoma is divided into small cell lung cancer (SCLC) and the other four types, conveniently labeled non–small cell lung cancer (NSCLC). This practical classification reflects different natural histories and different treatment. SCLC is prone to early hematogenous spread. It is rarely amenable to surgical resection and has a very aggressive course with a median survival (untreated) of 6–18 weeks. The four histologic categories comprising NSCLC spread more slowly. They may be cured in the early stages following resection, and for advanced disease, chemotherapy is tailored to specific histologies and molecular mutations found within NSCLC.

Clinical Findings

Lung cancer is symptomatic at diagnosis in 75–90% of patients. The clinical presentation depends on the type and location of the primary tumor, the extent of local spread, and the presence of distant metastases and any paraneoplastic syndromes.

A. Symptoms and Signs

Anorexia, weight loss, or asthenia occurs in 55–90% of patients presenting with a new diagnosis of lung cancer. Up to 60% of patients have a new cough or a change in a chronic cough; 6–31% have hemoptysis; and 25–40% complain of pain, either nonspecific chest pain or pain from bony metastases to the vertebrae, ribs, or pelvis. Local spread may cause endobronchial obstruction with atelectasis and postobstructive pneumonia, pleural effusion (12–33%), change in voice (compromise of the recurrent laryngeal nerve), superior vena cava syndrome (obstruction of the superior vena cava with supraclavicular venous engorgement), and Horner syndrome (ipsilateral ptosis, miosis, and anhidrosis from involvement of the inferior cervical ganglion and the paravertebral sympathetic chain). Distant metastases to the liver are associated with asthenia and weight loss. Brain metastases (10% in NSCLC, more common in adenocarcinoma, and 20–30% in SCLC) may present with headache, nausea, vomiting, seizures, dizziness, or altered mental status.

Paraneoplastic syndromes are incompletely understood patterns of organ dysfunction related to immune-mediated or secretory effects of neoplasms. These syndromes occur in 10–20% of lung cancer patients. They may precede, accompany, or follow the diagnosis of lung cancer and do not necessarily indicate metastatic disease. In patients with small cell carcinoma, the syndrome of inappropriate antidiuretic hormone (SIADH) can develop in 10–15%; in those with squamous cell carcinoma, hypercalcemia can develop in 10% (Table 39–2). Digital clubbing is seen in up to 20% of patients at diagnosis (see Figure 6–41). Other common paraneoplastic syndromes include increased ACTH production, anemia, hypercoagulability, peripheral neuropathy, and the Eaton-Lambert myasthenia syndrome. Their recognition is important because treatment of the primary tumor may improve or resolve symptoms even when the cancer is not curable.

B. Laboratory Findings

The diagnosis of lung cancer rests on examination of a tissue or cytology specimen. Sputum cytology is highly specific but insensitive; the yield is highest when there are lesions in the central airways. Thoracentesis (sensitivity 50–65%) can be used to establish a diagnosis of lung cancer in patients with malignant pleural effusions. If cytologic examination of an adequate sample (50–100 mL) of pleural fluid is nondiagnostic, the procedure should be repeated; approximately 30% of second samples are positive when the first sample is negative. If results remain negative, thoracoscopy is preferred to blind pleural biopsy. Fine-needle aspiration (FNA) of palpable supraclavicular or cervical lymph nodes is frequently diagnostic. Serum tumor markers are neither sensitive nor specific enough to aid in diagnosis.

Fiberoptic bronchoscopy allows visualization of the major airways, cytology brushing of visible lesions or lavage of lung segments with cytologic evaluation of specimens, direct biopsy of endobronchial abnormalities, blind transbronchial biopsy of the pulmonary parenchyma or peripheral nodules, and FNA biopsy of mediastinal lymph nodes. Diagnostic yield varies widely (10–90%) depending on the size of the lesion and its location. The use of fluorescence bronchoscopy improves the ability to identify early endobronchial lesions, while endobronchial and transesophageal endoscopic ultrasound enhance the direction and yield of FNA of mediastinal nodes. Transthoracic needle aspiration (TTNA) has a sensitivity between 50% and 97%. Mediastinoscopy, video-assisted thoracoscopic surgery (VATS), and thoracotomy are necessary in cases where less invasive techniques fail to yield a diagnosis.

C. Imaging

Nearly all patients with lung cancer have abnormal findings on chest radiography or CT scan. These findings are rarely specific for a particular diagnosis. Interpretation of characteristic findings in isolated nodules is described in Chapter 9.

D. Special Examinations

1. Staging—Accurate staging is crucial (1) to provide the clinician with information to guide treatment, (2) to provide the patient with accurate information regarding prognosis, and (3) to standardize entry criteria for clinical trials to allow interpretation of results.

There are two essential principles of staging NSCLC. First, the more extensive the disease, the worse the prognosis; second, surgical resection offers the best chance for cure. Staging of NSCLC uses two integrated systems. The TNM international staging system attempts a physical description of the neoplasm: T describes the size and location of the primary tumor; N describes the presence and location of nodal metastases; and M refers to the presence...
or absence of distant metastases. These TNM stages are grouped into prognostic categories (stages I–IV) using the results of clinical trials. This classification is used to guide therapy. Many patients with stage I and stage II disease are cured through surgery. Patients with stage IIIA and stage IV disease do not benefit from surgery (Table 39–3). Patients with stage IIIB disease have locally invasive disease that may benefit from surgery in certain circumstances.

SCLC is not staged using the TNM system because micrometastases are assumed to be present on diagnosis. SCLC is divided into two categories: limited disease (30%), when the tumor is limited to the unilateral hemithorax (including contralateral mediastinal nodes); or extensive disease (70%), when the tumor extends beyond the hemithorax (including pleural effusion). For both SCLC and NSCLC, staging begins with a thorough history and physical examination. A complete examination is essential to exclude obvious metastatic disease to lymph nodes, skin, and bone. A detailed history is essential because the patient’s performance status is a powerful predictor of disease course. All patients should have measurement of a complete blood count, electrolytes including calcium, creatinine, liver tests, lactate dehydrogenase, albumin, and a chest radiograph. Further evaluation will follow the results of these tests.

NSCLC patients being considered for surgery require meticulous evaluation to identify those with resectable disease. CT imaging is the most important modality for staging candidates for resection. A chest CT scan precisely defines the size of parenchymal lesions and identifies atelectatic lung or pleural effusions. However, CT imaging is less accurate at determining invasion of the chest wall (sensitivity 62%) or mediastinum (sensitivity 60–75%). The sensitivity and specificity of CT imaging for identifying lung cancer metastatic to the mediastinal lymph nodes are 57% (49–66%) and 82% (77–86%), respectively. Therefore, chest CT imaging does not provide definitive information on staging. CT imaging does help in making the decision about whether to proceed to resection of the primary tumor and sample the mediastinum at thoracotomy (common if there are no lymph nodes > 1 cm) or to use TTNA, mediastinoscopy, esophageal ultrasound with transesophageal needle aspiration, or limited thoracotomy to biopsy suspected metastatic disease (common where there are lymph nodes > 1–2 cm).

Positron emission tomography (PET) using 2-[18F] fluoro-2-deoxyglucose (FDG) is an important modality for identifying metastatic foci in the mediastinum or distant sites. The sensitivity and specificity of PET for detecting mediastinal spread of primary lung cancer depend on the size of mediastinal nodes or masses. When normal-sized (< 1 cm) mediastinal lymph nodes are present, the sensitivity and specificity of PET for tumor involvement of nodes are 74% and 96%, respectively. When CT shows enlarged (> 1 cm) lymph nodes, the sensitivity and specificity are 95% and 76%, respectively.

The combined modalities of PET and CT imaging have improved preoperative staging compared with CT or PET alone. Many lung cancer specialists find whole body fusion PET-CT imaging most useful to confirm lack of metastatic disease in NSCLC patients who are candidates for surgical resection. There is evidence that PET-CT imaging reduces futile thoracotomies by identifying mediastinal and distant metastases in patients with NSCLC. Disadvantages of PET imaging include limited resolution below 1 cm; the expense of FDG; limited availability; and false-positive scans due to sarcoidosis, tuberculosis, or fungal infections. PET-CT scans are also inadequate for evaluating brain metastases due to the high FDG uptake there. Obtaining an MRI of the brain is important to rule out brain metastases in patients with at least stage II disease.

†Independent of therapy, generally not surgical patients.

exercise testing may be helpful. A maximal oxygen uptake (\(\dot{V}_{O_2}\)) of > 15 mL/kg/min identifies patients with an acceptable incidence of complications and mortality. Patients with a \(\dot{V}_{O_2}\) of < 10 mL/kg/min have a very high mortality rate at thoracotomy. Hypoxemia and hypercapnia are not independent predictors of outcome.

4. Screening—Prior data showed that chest radiographs and analysis of expectorated sputum as lung cancer screening modalities did not improve survival. The National Lung Screening Trial, a multicenter randomized national trial involving over 53,000 current and former heavy smokers, published results showing a 20% reduction in lung cancer deaths. It compared low-dose helical CT with standard chest radiographs as screening modalities for lung cancer. Given these findings, clinical guidelines and policy recommendations on lung cancer screening are currently being discussed. Risk-benefit and cost-effective analyses are underway. The implications of widespread screening of smokers raise issues of false positives (96% in this study), surgical and medical complications from additional testing, risks of cumulative exposure to radiation, and risks of increasing patient anxiety and stress on an already limited pool of resources.

▶ Treatment

A. Non–Small Cell Carcinoma

Cure of NSCLC is unlikely without resection. Therefore, the initial approach to the patient is determined by the answers to two questions: (1) Is complete surgical resection technically feasible? (2) If yes, is the patient able to tolerate the surgery with acceptable morbidity and mortality? Clinical features that preclude complete resection include extrathoracic metastases or a malignant pleural effusion; or tumor involving the heart, pericardium, great vessels, esophagus, recurrent laryngeal or phrenic nerves, trachea, main carina, or contralateral mediastinal lymph nodes. Accordingly, stage I and stage II patients are treated with surgical resection where possible. Stage II, and possibly a subset of stage IB, are additionally recommended to receive adjuvant chemotherapy. Stage IIIA patients have poor outcomes when treated with resection alone. They should be referred to multimodality protocols, including chemotherapy or radiotherapy, or both. Stage IIIB patients treated with concurrent chemotherapy and radiation therapy have improved survival. Stage IV patients are treated with chemotherapy or symptom-based palliative therapy, or both (see below).

Surgical approach affects outcome. The North American Lung Cancer Study Group conducted a prospective trial of stage I A patients randomized to lobectomy versus limited resection. They reported a threefold increased rate of local recurrence in the limited resection group \((P = 0.008)\) and a trend toward an increase in overall death rate \((increase of 30\%, P = 0.08)\) and increase in death rate due to cancer \((increase of 50\%, P = 0.09)\), compared with patients receiving lobectomy. There are inadequate outcome data on which to base a comparison of VATS with standard thoracotomy. Radiation therapy following surgery improves local control but does not improve survival.

Patients with small early-stage primary lung cancers who are not candidates for surgery because of significant comorbidity or other surgical contraindication may be candidates for stereotactic body radiotherapy. Stereotactic body radiotherapy (cyberknife), which is composed of multiple non-parallel radiation beams that converge, allows the delivery of a relatively large dose of radiation to a small, well-defined target. For small, early-stage cancers, 3-year local control rates with cyberknife exceed 90%, and 3-year survival is estimated at over 55%. Patients with locally advanced disease (stages IIIA and IIIB) who are not surgical candidates have improved survival when treated with concurrent chemotherapy and radiation therapy compared with no therapy, radiation alone, or even sequential chemotheraphy and radiation.

Neoadjuvant chemotherapy consists of giving antineoplastic drugs in advance of surgery or radiation therapy. There is no consensus on the impact of neoadjuvant therapy on survival in stage I and stage II NSCLC. Such therapy is not recommended outside of ongoing clinical trials. Neoadjuvant therapy is more widely used in selected patients with stage IIIA or stage IIIB disease. Some studies suggest a survival advantage. This remains an area of active research.

Adjuvant chemotherapy consists of administering antineoplastic drugs following surgery or radiation therapy. Cisplatin-containing regimens have been shown to confer an overall survival benefit in at least stage II disease and possibly a subset of stage IB disease. The Lung Adjuvant Cisplatin Evaluation Collaborative Group published a meta-analysis of the five largest cisplatin-based adjuvant trials. They reported a 3% absolute benefit in 5-year overall survival with a cisplatin-containing doublet regimen following surgery \((P = 0.005)\) in patients with at least stage II disease. For patients with poor performance status (Eastern Cooperative Oncology Group Score ≤ 2), there is no evidence of survival benefit for adjuvant chemotherapy; rather, it may be detrimental. Novel targeted agents with less toxicity are in clinical trials, and gene expression profiling has shown promise in defining a subset of patients who may benefit from adjuvant therapy.

Although not curative, chemotherapy has been shown in multiple clinical trials to provide a modest increase in overall survival and performance status in patients with stage IIIB and stage IV NSCLC compared with supportive care alone, with median survival increased from 5 months to a range of 7–11 months. Palliative chemotherapy also leads to improved quality of life and symptom control, with first-line therapy involving a platinum-based regimen. Platinum-based doublet regimens consist of cisplatin or carboplatin (agents that bind DNA to form adducts that inhibit their synthesis and function) combined with another agent, such as gemcitabine, taxane, vinorelbine, or pemetrexed. When compared in phase III trials for advanced NSCLC, these doublet regimens have shown comparable efficacy with varying toxicity profiles. Investigators have shown that the choice of chemotherapeutic agent can be tailored to histologic subtype in NSCLC. For nonsquamous histologies, patients have modestly improved overall survival when treated with a platinum agent plus pemetrexed.
(an inhibitor of folate-dependent enzymes important in purine and pyrimidine synthesis). Patients with squamous cell lung carcinomas have modestly improved overall survival when a platinum agent is combined with gemcitabine (a deoxycytidine analog that inhibits DNA synthesis). For good performance status patients with nonsquamous histologies, bevacizumab (a monoclonal antibody to vascular endothelial growth factor [VEGF]) can be added to a traditional platinum doublet regimen with further modest increase in survival benefit. Cetuximab (a monoclonal antibody to the epidermal growth factor receptor [EGFR]) added to a platinum doublet regimen for all histologies of NSCLC has also shown a small survival benefit.

With the advent of molecular profiling, targeted therapy has played a significant role in NSCLC. For the subgroup of patients with EGFR mutations, an EGFR inhibitor (erlotinib and gefitinib) rather than platinum-based chemotherapy is the first-line treatment. Response rates with EGFR inhibitors in patients with EGFR mutation are at least 60%, and median overall survival is estimated at 27–30 months. EGFR mutations are found in approximately 10–15% of the white population and 30–40% in the Asian population and are usually found among nonsmokers to light-smokers, females, and adenocarcinoma histology. Approximately 5% of all patients with NSCLC carry a different mutation, the EML4-ALK fusion gene product. This is found in a comparatively younger population, with adenocarcinoma histology, and nonsmoking to light-smoking history. Based on early single-arm trials showing 60% response rates, crizotinib, an ALK and MET inhibitor, was approved by the US Food and Drug Administration (FDA) to treat EML4-ALK–positive NSCLCs. Finally, KRAS mutations are found among 25% of patients with adenocarcinomas, are associated with smoking, indicate a poor prognosis, and typically do not respond to EGFR inhibition. These three mutations are mutually exclusive. Ongoing research seeks to define the role of these targeted agents in early stage and locally advanced lung cancers, and identification of new novel mutations.

B. Small Cell Carcinoma

Response rates of SCLC to cisplatin and etoposide are excellent with 80–90% response in limited-stage disease (50–60% complete response), and 60–80% response in extensive stage disease (15–20% complete response). However, remissions tend to be short-lived with a median duration of 6–8 months. Once the disease has recurred, median survival is 3–4 months. Overall 2-year survival is 20–40% in limited-stage disease and < 5% in extensive-stage disease. Thoracic radiation therapy improves survival in patients with limited SCLC and is given concurrently with chemotherapy. Thoracic radiation therapy is not beneficial for patients with extensive disease, and they should receive chemotherapy alone. There is a high rate of brain metastasis in patients with SCLC, even following a good response to chemotherapy, because chemotherapy does not adequately penetrate the blood-brain barrier. Prophylactic cranial irradiation has been shown to decrease the incidence of central nervous system disease and improve survival in patients with limited stage disease who respond to chemotherapy and a subset of patients with extensive stage disease who have had an excellent response to chemotherapy.

Occasionally, a patient may have a peripheral nodule resected that turns out to be SCLC. Five-year survival following resection of the equivalent of stage I and stage II SCLC is higher than in patients treated with chemotherapy.

C. Palliative Therapy

Photoresection with the Nd:YAG laser is sometimes performed on central tumors to relieve endobronchial obstruction, improve dyspnea, and control hemoptysis. External beam radiation therapy is also used to control dyspnea, hemoptysis, endobronchial obstruction, pain from bony metastases, obstruction from superior vena cava syndrome, and symptomatic brain metastases. Resection of a solitary brain metastasis improves quality of life when combined with radiation therapy, and if there is no evidence of other metastatic disease, it may improve survival. Intraluminal radiation (brachytherapy) is an alternative approach to endobronchial disease. Pain syndromes are very common in advanced disease. As patients approach the end of life, meticulous efforts at pain control are essential (see Chapter 5). In addition to standard oncologic care, early consultation with—or referral to—a palliative care specialist is recommended in advanced disease to aid in symptom management; it may even modestly improve survival.

Prognosis

The overall 5-year survival rate for lung cancer is approximately 15%. Predictors of survival include the type of tumor (SCLC versus NSCLC), molecular typing, the stage of the tumor, the patient’s performance status, and weight loss in the past 6 months. Patients with EGFR mutation have better overall survival when compared with those without EGFR mutation, even when receiving similar cytotoxic chemotherapy.

For example, an elevated prostate-specific antigen (PSA) may indicate prostate cancer, carcinoembryonic antigen (CEA) tests for colorectal cancer, and β-human chorionic gonadotropin (βHCG) and α-fetoprotein test for germ cell tumors. Based on the clinical setting, imaging studies should be ordered (see below). If the history, physical examination, and initial studies fail to reveal the site of the primary tumor, attention is better focused on the lung, where tissue samples obtained by bronchoscopy, percutaneous needle biopsy, VATS, or thoracotomy may establish the histologic diagnosis and suggest the most likely primary cancer. Occasionally, cytologic studies of pleural fluid or pleural biopsy reveal the diagnosis. Sputum cytology is rarely helpful.

If the initial histologic review does not reveal a primary diagnosis, immunohistochemical staining should be done on the biopsy specimen. For example, PSA and thyroglobulin staining are highly specific for prostate and thyroid cancer, respectively. Thyroid transcription factor-1 (TTF-1) is relatively specific for primary lung adenocarcinoma, while also positive for SCLC and thyroid carcinoma. An adenocarcinoma that demonstrates negative TTF-1 staining strongly suggests a nonpulmonary primary cancer. Positive estrogen receptor (ER) and progesterone receptor (PR) stains suggest primary breast cancer.

### C. Imaging

Chest radiographs usually show multiple spherical densities with sharp margins. The size of metastatic lesions varies from a few millimeters (miliary densities) to large masses. Nearly all are < 5 cm in diameter. The lesions are usually bilateral, plural or subpleural in location, and more common in lower lung zones. Cavitation suggests squamous cell tumor; calcification suggests osteosarcoma. Lymphangitic spread and solitary pulmonary nodule are less common radiographic presentations of pulmonary metastasis. Conventional chest radiography is less sensitive than CT scan in detecting pulmonary metastases. Mammography should be considered in women to search for possible primary breast cancer. CT imaging of the chest, abdomen, and pelvis may reveal the site of a primary tumor and will help determine feasibility of surgical resection of the metastatic lung tumors. PET-CT scan may also help in identifying the site of a primary cancer or identifying other areas of extrathoracic metastasis.

### Treatment

Once the diagnosis has been established, management consists of treatment of the primary neoplasm and any pulmonary complications. Surgical resection of a solitary pulmonary nodule is often prudent in the patient with known current or previous extrapulmonary cancer. Local resection of one or more pulmonary metastases is feasible in a few carefully selected patients with various sarcomas and carcinomas (breast, testis, colon, and kidney). Surgical resection should be considered only if the primary tumor is under control, if the patient is a good surgical risk, if all of the metastatic tumor can be resected, if effective nonsurgical approaches are not available, and if there are no
metastases elsewhere in the body. Relative contraindications to resection of pulmonary metastases include (1) malignant melanoma primary, (2) requirement for pneumonectomy, and (3) pleural involvement. Data from the International Registry of Lung Metastases report an overall 5-year survival rate of 36% and 10-year survival rate of 26% after complete resection of pulmonary metastases. Patients who are not surgical candidates but have solitary or limited metastatic disease to the lungs may be candidates for stereotactic radiosurgery, radioablation, or cryotherapy. For patients with progressive disease, diligent attention to palliative care is essential (see Chapter 5).

Clinical Findings

A. Symptoms and Signs

The average interval between onset of symptoms and diagnosis is 2–3 months; the median age at diagnosis is 69 years in Western countries. Symptoms include the insidious onset of shortness of breath, nonpleuritic chest pain, and weight loss. Physical findings include dullness to percussion, diminished breath sounds and, in some cases, digital clubbing.

B. Laboratory Findings

Pleural fluid is exudative and often hemorrhagic. Cytologic tests of pleural fluid are often negative. VATS biopsy is usually necessary to obtain an adequate specimen for histologic diagnosis. The histologic variants of malignant pleural mesothelioma are epithelial (50–60%), sarcomatoid (10%), and biphasic (30–40%). Since distinction from benign inflammatory conditions and metastatic adenocarcinoma may be difficult, immunohistochemical stains are important to confirm the diagnosis. Epithelial mesothelioma stains are positive for pankeratin, calretinin, keratin 5/6, and WT1 and are negative for epithelial markers, such as CEA, MOC-31, TTF-1, CD15, and B72.3 (usually three needed). Soluble mesothelin-related peptide also may be found in serum or pleural fluid (or both) of patients with mesothelioma, epithelioid type.

C. Imaging

Radiographic abnormalities consist of nodular, irregular, unilateral pleural thickening and varying degrees of unilateral pleural effusion. Sixty percent of patients have right-sided disease, while only 5% have bilateral involvement. CT scans demonstrate the extent of pleural involvement. PET-CT is increasingly used to help differentiate benign from malignant pleural disease, improve staging accuracy, and identify candidates for aggressive surgical approaches.

Complications

Malignant pleural mesothelioma progresses rapidly as the tumor spreads along the pleural surface to involve the pericardium, mediastinum, and contralateral pleura. The tumor may eventually extend beyond the thorax to involve abdominal lymph nodes and organs. Progressive pain and dyspnea are characteristic. Local invasion of thoracic
structures may cause superior vena cava syndrome, hoarseness, Horner syndrome, arrhythmias, and dysphagia. Paraneoplastic syndromes associated with mesothelioma include thrombocytosis, hemolytic anemia, disseminated intravascular coagulopathy, hypercalcemia, and migratory thrombophlebitis.

**Treatment**

Chemotherapy is the mainstay of treatment, unless there is localized disease that can be surgically resected. Surgery, radiotherapy, chemotherapy, or a combination of modalities may be attempted, but treatments are generally unsuccessful. For localized disease, pleurectomy and decortication (surgical stripping of the pleura and pericardium from apex of the lung to diaphragm) is one surgical approach and can be effective in controlling malignant pleural effusion. Previously, some thoracic surgeons favored a trimodality approach for localized disease with extrapleural pneumonectomy, adjuvant radiation, and chemotherapy, based on limited retrospective data that it prolongs survival in highly selected patients. Extrapleural pneumonectomy is a radical surgical procedure involving removal of the ipsilateral lung, parietal and visceral pleura, pericardium, and most of the hemidiaphragm. However, the Mesothelioma and Radical Surgery (MARS) trial, a small randomized study comparing extrapleural pneumonectomy with no extrapleural pneumonectomy after induction chemotherapy in 50 patients, showed that extrapleural pneumonectomy offered no survival benefit and may have caused more harm. In advanced unresectable cases, palliative chemotherapy with cisplatin and pemetrexed can extend survival as well as improve quality of life. Other alternative chemotherapy regimens include gemcitabine, anthracyclines, or vinorelbine. Drainage of pleural effusions, pleurodesis, radiation therapy, and even surgical resection may offer palliative benefit in some patients.

**Prognosis**

Most patients die of respiratory failure and complications of local extension. Median survival time from onset of symptoms ranges from 4 months in extensive disease to 16 months in localized disease. Five-year survival is < 5%. Tumors that are predominantly sarcomatoid are more resistant to therapy and have a worse prognosis, with median survivals < 1 year. Poor prognostic features include poor performance status, non-epithelioid histology, male gender, nodal involvement, elevated lactate dehydrogenase, high white blood cell count, low hemoglobin, and high platelet count.

**References**

**HEPATOBILIARY CANCERS**

**HEPATOCELLULAR CARCINOMA**

**Essentials of Diagnosis**

- In Western countries, usually a complication of cirrhosis.
- Characteristic CT and MRI features and elevated serum α-fetoprotein may obviate the need for a confirmatory biopsy.

**General Considerations**

Malignant neoplasms of the liver that arise from parenchymal cells are called hepatocellular carcinomas; those that originate in the ductular cells are called cholangiocarcinomas. Hepatocellular carcinomas are associated with cirrhosis in 80% of cases. Incidence rates are rising rapidly (twofold since 1978) in the United States and other Western countries, presumably because of the increasing prevalence of cirrhosis caused by chronic hepatitis C infection and non-alcoholic fatty liver disease. In Western countries, risk factors for hepatocellular carcinoma in patients known to have cirrhosis are male gender, age > 55 years (although there has been an increase in the number of younger cases), Asian or Hispanic ethnicity, family history in a first-degree relative, overweight, obesity, alcohol use (especially in combination with obesity), diabetes mellitus, hypothyroidism (in women), HCV infection, HBsAg and anti-HBc positivity, a prolonged prothrombin time, a low platelet count, and an elevated serum transferrin saturation. In Africa and most of Asia, hepatitis B is of major etiologic significance, whereas in Western countries and Japan, hepatitis C (particularly genotype 1b and sometimes in combination with “occult” HBV infection) and alcoholic cirrhosis are the most common risk factors. Other associations include high levels of HBV replication, HBV genotype C, hepatitis D coinfection, hemochromatosis (and possibly the C282Y carrier state), aflatoxin exposure (associated with mutation of the TP53 gene),
α₁-antitrypsin (α₁-antitrypsin) deficiency, tyrosinemia, and radiation exposure. In patients with the metabolic syndrome, hepatocellular carcinoma may arise from a hepatocellular adenoma in the absence of cirrhosis. Evidence for an association with long-term use of oral contraceptives is inconclusive. Coffee consumption and, in diabetic patients, the use of statins appear to be protective. The fibrolamellar variant of hepatocellular carcinoma occurs in young women and is characterized by a distinctive histologic picture, absence of risk factors, and indolent course. Vinyl chloride exposure is associated with angiosarcoma of the liver.

Clinical Findings

A. Symptoms and Signs

The presence of a hepatocellular carcinoma may be unsuspected until there is deterioration in the condition of a cirrhotic patient who was formerly stable. Cachexia, weakness, and weight loss are associated symptoms. The sudden appearance of ascites, which may be bloody, suggests portal or hepatic vein thrombosis by tumor or bleeding from a necrotic tumor.

Physical examination may show tender enlargement of the liver, occasionally with a palpable mass. In Africa, the typical presentation in young patients is a rapidly expanding abdominal mass. Auscultation may reveal a bruit over the tumor or a friction rub when the tumor has extended to the surface of the liver.

B. Laboratory Findings

Laboratory tests may reveal leukocytosis, as opposed to the leukopenia that is frequently encountered in cirrhotic patients. Anemia is common, but a normal or elevated hematocrit value may be found in up to one-third of patients owing to elaboration of erythropoietin by the tumor. Sudden and sustained elevation of the serum alkaline phosphatase in a patient who was formerly stable is a common finding. HBsAg is present in a majority of cases in endemic areas, whereas in the United States anti-HCV is found in up to 40% of cases. Lesions smaller than 1 cm may be difficult to characterize. Arterial phase enhancement of the lesion followed by delayed hypointensity (“washout”) is most specific for hepatocellular carcinoma. Ultrasonography is less sensitive and operator dependent but is used to screen for hepatic nodules in high-risk patients. Contrast-enhanced ultrasonography has a sensitivity and specificity approaching those of arterial phase helical CT but, unlike CT and MRI, cannot image the entire liver during the short duration of the arterial phase and is associated with false-positive results. In selected cases, endoscopic ultrasonography may be useful. PET is under study.

D. Liver Biopsy and Staging

Liver biopsy is diagnostic, although seeding of the needle tract by tumor is a potential risk (1–3%). For lesions < 1 cm, ultrasonography may be repeated every 3 months followed by further investigation of enlarging lesions. For lesions ≥ 1 cm, biopsy can be deferred when characteristic arterial hypervascularity and delayed washout are demonstrated on either multiphasic helical CT or MRI with contrast enhancement (or both) or if surgical resection is planned. Staging in the TNM classification includes the following definitions: T0: no evidence of primary tumor; T1: solitary tumor without vascular invasion; T2: solitary tumor with vascular invasion or multiple tumors none more than 5 cm; T3: multiple tumors more than 5 cm (3a) or tumor involving a major branch of the portal or hepatic vein (3b); and T4: tumor(s) with direct invasion of adjacent organs other than the gallbladder or with perforation of the visceral peritoneum; N1, regional lymph node metastasis; M1, distant metastasis; F0, no to moderate hepatic fibrosis; F1, severe hepatic fibrosis to cirrhosis. The Barcelona Clinic Liver Cancer (BCLC) staging system is preferred and includes the Child-Turcotte-Pugh stage, tumor stage, and liver function and has the advantage of linking overall stage with preferred treatment modalities and with an estimation of life expectancy.

Screening & Prevention

In the patient with chronic hepatitis B (beginning as early as age 20 in Africans and age 40 in Asians or those with a family history of hepatocellular carcinoma) or cirrhosis caused by HCV, HBV, or alcohol, surveillance for the development of hepatocellular carcinoma is recommended. Although the standard approach is α-fetoprotein testing and ultrasonography every 6 months, the value of α-fetoprotein screening has been questioned because of its low sensitivity. CT and MRI are considered too expensive for screening, but the sensitivity of ultrasonography for detecting early hepatocellular carcinoma is only 63%. The risk of hepatocellular carcinoma in a patient with cirrhosis is 3–5% a year, and patients with tumors detected by surveillance have a less advanced stage on average and greater likelihood that treatment will prolong survival than those not undergoing surveillance. In a population of patients with cirrhosis, over 60% of nodules < 2 cm in diameter detected on a screening ultrasonography prove to be hepatocellular carcinoma. Mass vaccination programs against

1 cm may be difficult to characterize. Arterial phase enhancement of the lesion followed by delayed hypointensity (“washout”) is most specific for hepatocellular carcinoma. Ultrasonography is less sensitive and operator dependent but is used to screen for hepatic nodules in high-risk patients. Contrast-enhanced ultrasonography has a sensitivity and specificity approaching those of arterial phase helical CT but, unlike CT and MRI, cannot image the entire liver during the short duration of the arterial phase and is associated with false-positive results. In selected cases, endoscopic ultrasonography may be useful. PET is under study.

D. Liver Biopsy and Staging

Liver biopsy is diagnostic, although seeding of the needle tract by tumor is a potential risk (1–3%). For lesions < 1 cm, ultrasonography may be repeated every 3 months followed by further investigation of enlarging lesions. For lesions ≥ 1 cm, biopsy can be deferred when characteristic arterial hypervascularity and delayed washout are demonstrated on either multiphasic helical CT or MRI with contrast enhancement (or both) or if surgical resection is planned. Staging in the TNM classification includes the following definitions: T0: no evidence of primary tumor; T1: solitary tumor without vascular invasion; T2: solitary tumor with vascular invasion or multiple tumors none more than 5 cm; T3: multiple tumors more than 5 cm (3a) or tumor involving a major branch of the portal or hepatic vein (3b); and T4: tumor(s) with direct invasion of adjacent organs other than the gallbladder or with perforation of the visceral peritoneum; N1, regional lymph node metastasis; M1, distant metastasis; F0, no to moderate hepatic fibrosis; F1, severe hepatic fibrosis to cirrhosis. The Barcelona Clinic Liver Cancer (BCLC) staging system is preferred and includes the Child-Turcotte-Pugh stage, tumor stage, and liver function and has the advantage of linking overall stage with preferred treatment modalities and with an estimation of life expectancy.

Screening & Prevention

In the patient with chronic hepatitis B (beginning as early as age 20 in Africans and age 40 in Asians or those with a family history of hepatocellular carcinoma) or cirrhosis caused by HCV, HBV, or alcohol, surveillance for the development of hepatocellular carcinoma is recommended. Although the standard approach is α-fetoprotein testing and ultrasonography every 6 months, the value of α-fetoprotein screening has been questioned because of its low sensitivity. CT and MRI are considered too expensive for screening, but the sensitivity of ultrasonography for detecting early hepatocellular carcinoma is only 63%. The risk of hepatocellular carcinoma in a patient with cirrhosis is 3–5% a year, and patients with tumors detected by surveillance have a less advanced stage on average and greater likelihood that treatment will prolong survival than those not undergoing surveillance. In a population of patients with cirrhosis, over 60% of nodules < 2 cm in diameter detected on a screening ultrasonography prove to be hepatocellular carcinoma. Mass vaccination programs against
HBV in developing countries are leading to reduced rates of hepatocellular carcinoma. Successful treatment of hepatitis B and of hepatitis C in patients with cirrhosis also reduces the subsequent risk of hepatocellular carcinoma.

**Treatment**

Surgical resection of a solitary hepatocellular carcinoma may result in cure if liver function is preserved (Child class A or possibly B) and portal vein thrombosis is not present. Laparoscopic liver resection has been performed in selected cases. Treatment of underlying chronic viral hepatitis, adjuvant chemotherapy, and adaptive immunotherapy may lower postsurgical recurrence rates. Liver transplantation may be appropriate for small unresectable tumors in a patient with advanced cirrhosis, with reported 5-year survival rates of up to 75%. The recurrence-free survival may be better for liver transplantation than for resection in patients with well-compensated cirrhosis and small tumors (one tumor < 5 cm or three or fewer tumors each < 3 cm in diameter [Milan criteria]) and in those with expanded (University of California, San Francisco) criteria of one tumor ≤ 6.5 cm or three or fewer tumors ≤ 4.5 cm. Patients with stage 2 hepatocellular carcinoma receive an additional 22 points on their Model for End-Stage Liver Disease (MELD) score (see Chapter 16), markedly increasing their chances of undergoing transplantation. However, liver transplantation is often impractical because of the donor organ shortage, and living donor liver transplantation may be considered in these cases. Patients with larger tumors (3–5 cm), a serum α-fetoprotein level ≥ 455 ng/mL, or a MELD score ≥ 20 have poor posttransplantation survival. Chemotherapy, hormonal therapy with tamoxifen, and long-acting octreotide have not been shown to prolong life, but transarterial chemoembolization (TACE), transarterial chemoinfusion (TACI), and transarterial radioembolization (TARE) via the hepatic artery are palliative and may prolong survival in patients with a large or multifocal tumor in the absence of extrhepatic spread. TACI and TARE are suitable for patients with portal vein thrombosis. Injection of absolute ethanol into, radiofrequency ablation of, cryotherapy of, or microwave ablation of small tumors (< 2 cm) may prolong survival in patients who are not candidates for resection; these interventions may provide a “bridge” to liver transplantation. Radiofrequency ablation is superior to ethanol injection for tumors > 2 cm in diameter and can be performed after TACE in select cases. Sorafenib (an oral multikinase inhibitor of Raf kinase, the VEGF receptor, and the platelet-derived growth factor receptor [and others]), prolongs median survival as well as the time to radiologic progression by 3 months in patients with advanced hepatocellular carcinoma; sorafenib is the standard of care in these patients. New chemotherapies and radiation therapy techniques (eg, radioembolization with yttrium-90 microspheres), novel biologic approaches (eg, bortezomib, a proteasome inhibitor; antiangiogenesis agents; other inhibitors of growth-factor signaling; and gene therapy), and multimodal approaches are under study. For patients whose disease progresses despite treatment or who present with advanced tumors, vascular invasion, or extrahepatic spread, meticulous efforts at palliative care are essential (see Chapter 5). Severe pain may develop in such patients due to expansion of the liver capsule by the tumor and requires concerted efforts at pain management, including the use of opioids (see Chapter 5).

**Prognosis**

In the United States, overall 1- and 5-year survival rates for patients with hepatocellular carcinoma are 23% and 5%, respectively. Five-year survival rates rise to 56% for patients with localized resectable disease (T1, T2, selected T3 and T4; N0; M0) but are virtually nil for those with locally unresectable or advanced disease. In patients with HCV-related hepatocellular carcinoma, the serum α-fetoprotein level at the time of diagnosis of cancer has been reported to be an independent predictor of mortality. Contrary to traditional opinion, the fibrolamellar variant does not have a better prognosis than conventional hepatocellular carcinoma without cirrhosis.

**When to Refer**

All patients with hepatocellular carcinoma should be referred to a specialist.

**When to Admit**

- Complications of cirrhosis.
- Severe pain.
- For surgery and other interventions.

---

**Carcinoma of the Biliary Tract**

**ESSENTIALS OF DIAGNOSIS**

- Presents with obstructive jaundice, usually painless, often with dilated biliary tree.
- Pain is more common in gallbladder carcinoma than cholangiocarcinoma.
- A Courvoisier (dilated) gallbladder may be detected.
- Diagnosis by cholangiography with biopsy and brushings for cytology.

**General Considerations**

Carcinoma of the gallbladder occurs in approximately 2% of all people operated on for biliary tract disease. It is
notoriously insidious, and the diagnosis is often made unexpectedly at surgery. Cholelithiasis (often large, symptomatic stones) is usually present. Other risk factors are chronic infection of the gallbladder with Salmonella typhi, gallbladder polyps over 1 cm in diameter, mucosal calcification of the gallbladder (porcelain gallbladder), and anomalous pancreaticobiliary ductal junction. Genetic factors include K-ras and TP53 mutations. Spread of the cancer—by direct extension into the liver or to the peritoneal surface—may be the initial manifestation. The TNM classification includes the following stages: Tis, carcinoma in situ; T1a, tumor invades lamina propria, and T1b, tumor invades muscle layer; T2, tumor invades peri muscular connective tissue, no extension beyond serosa (visceral peritoneum) or into liver; T3, tumor perforates the serosa or directly invades the liver or adjacent organ or structure; T4, tumor invades the main portal vein or hepatic artery or invades multiple extrahepatic organs or structures; N1, regional lymph node metastasis; and M1, distant metastasis.

Carcinoma of the bile ducts (cholangiocarcinoma) accounts for 10–25% of all hepatobiliary malignancies and 3% of all cancer deaths in the United States. It is more prevalent in persons aged 50–70, with a slight male predominance, and more common in Asia. Two-thirds arise at the confluence of the hepati ducts (Klatskin tumors), and one-fourth arise in the distal extrahepatic bile duct; the remainder are intrahepatic (peripheral), the incidence of which has risen dramatically since the 1970s. Staging for extrahepatic cholangiocarcinoma is as follows: T1, tumor is confined to bile duct; T2, tumor spreads beyond the wall of the bile duct (2a) or to the adjacent liver (2b); T3, tumor spreads to unilateral branches of the portal vein or hepatic artery; T4, tumor spreads to main portal vein or its branches bilaterally, common hepatic artery, second-order biliary radicals bilaterally, or various combinations; N1, regional lymph node metastasis; M1, distant metastasis. Staging for intrahepatic cholangiocarcinoma is as follows: T1, solitary tumor without vascular invasion; T2, solitary tumor with vascular invasion or multiple tumors ≤ 5 cm; T3, multiple tumors > 5 cm or involving major branch of portal or hepatic veins; T4, tumor invades adjacent organ (except gallbladder) or perforation of visceral peritoneum; N1, regional lymph node metastasis; and M1, distant metastasis. Other staging systems consider tumor extent and form, vascular encasement, hepatic lobe atrophy, and underlying liver disease. The frequency of carcinoma in persons with choledochal cysts has been reported to be over 14% at 20 years, and surgical excision is recommended. There is an increased incidence in patients with bile duct adenoma; biliary papillomatosis; Caroli disease; a biliary-enteric anastomosis; ulcerative colitis, especially those with primary sclerosing cholangitis; biliary cirrhosis; diabetes mellitus; hyperthyroidism; chronic pancreatitis; heavy alcohol consumption; and past exposure to thioracetam, a contrast agent. In Southeast Asia, hepatolithiasis and infection of the bile ducts with helminths (Clonorchis sinensis, Opisthorchis viverrini) are associated with chronic cholangitis and an increased risk of cholangiocarcinoma. Hepatitis C virus infection, cirrhosis, HIV infection, nonalcoholic fatty liver disease, diabetes mellitus, obesity, and tobacco smoking are additional risk factors for intrahepatic cholangiocarcinoma.

Clinical Findings
A. Symptoms and Signs
Progressive jaundice is the most common and usually the first sign of obstruction of the extrahepatic biliary system. Pain in the right upper abdomen with radiation into the back is usually present early in the course of gallbladder carcinoma but occurs later in the course of bile duct carcinoma. Anorexia and weight loss are common and may be associated with fever and chills due to cholangitis. Rarely, hematolemia or melena results from erosion of tumor into a blood vessel (hemobilia). Fistula formation between the biliary system and adjacent organs may also occur. The course is usually one of rapid deterioration, with death occurring within a few months.

Physical examination reveals profound jaundice. Pruritus and skin excoriations are common. A palpable gallbladder with obstructive jaundice usually is said to signify malignant disease (Courvoisier law); however, this clinical generalization has been proved to be accurate only about 50% of the time. Hepatomegaly due to hypertrophy of the unobstructed liver lobe is usually present and is associated with liver tenderness. Ascites may occur with peritoneal implants.

B. Laboratory Findings
With biliary obstruction, laboratory examination reveals predominantly conjugated hyperbilirubinemia, with total serum bilirubin values ranging from 5 to 30 mg/dL. There is usually concomitant elevation of the alkaline phosphotase and serum cholesterol. AST is normal or minimally elevated. An elevated CA 19-9 level may help distinguish cholangiocarcinoma from a benign biliary stricture (in the absence of cholangitis).

C. Imaging
Ultrasoundography and contrast-enhanced, triple-phase, helical CT may show a gallbladder mass in gallbladder carcinoma and intrahepatic mass or biliary dilatation in carcinoma of the bile ducts. CT may also show involved regional lymph nodes and atrophy of a hepatic lobe because of vascular encasement with compensatory hypertrophy of the unaffected lobe. MRI with magnetic resonance cholangiopancreatography (MRCP) and gadolinium enhancement permits visualization of the entire biliary tree and detection of vascular invasion and obviates the need for angiography and, in some cases, direct cholangiography; it is the imaging procedure of choice but may understage malignant hilar strictures. The sensitivity and image quality can be increased with use of ferumoxide enhancement. The features of intrahepatic cholangiocarcinoma on MRI appear to differ from those of hepatocellular carcinoma, with contrast washout in the latter but not the former. In indeterminate cases, PET can detect cholangiocarcinomas as small as 1 cm and lymph node and
distant metastases, but false-positive results occur. The most helpful diagnostic studies before surgery are either percutaneous transhepatic or endoscopic retrograde cholangiography with biopsy and cytologic specimens, although false-negative biopsy and cytology results are common. Digital image analysis and fluorescent in situ hybridization of cytologic specimens improve sensitivity. Endoscopic ultrasonography with FNA of tumors, choledochoscopy, and intraductal ultrasonography may confirm a diagnosis of cholangiocarcinoma in a patient with bile duct stricture and an otherwise indeterminate evaluation.

Treatment

In young and fit patients, curative surgery may be attempted if the tumor is well localized. The 5-year survival rate for carcinoma of the gallbladder invading the lamina propria or muscularis (stage I, T1a or 1b, N0, M0) is as high as 85% with laparoscopic cholecystectomy but drops to 60%, even with a more extended open resection, if there is peri-肌ural invasion (T2). The role of radical surgery for T3 and T4 tumors is debatable. If the tumor is unresectable at laparotomy, biliary-enteric bypass (eg, Roux-en-Y hepaticojejunostomy) can be performed. Carcinoma of the bile ducts is curable by surgery in <10% of cases. If resection margins are negative, the 5-year survival rate may be as high as 47% for intrahepatic cholangiocarcinomas, 41% for hilar cholangiocarcinoma, and 37% for distal cholangiocarcinomas, but the perioperative mortality rate may be as high as 10%. Palliation can be achieved by placement of a self-expandable metal stent via an endoscopic or percutaneous transhepatic route. Covered metal stents may be more cost-effective than uncovered metal stents because of a longer duration of patency, but they are associated with a higher rate of stent migration and cholecystitis due to occlusion of the cystic duct and are not associated with longer survival. For hilar tumors, there is controversy as to whether unilateral or bilateral stents should be inserted. Plastic stents are less expensive but more prone to occlude than metal ones; they are suitable for patients expected to survive only a few months. Photodynamic therapy in combination with stent placement has been demonstrated to prolong survival when compared with stent placement alone in patients with unresectable cholangiocarcinoma. Radiotherapy may relieve pain and contribute to biliary decompression. There is limited response to chemotherapy with gemcitabine alone, but the combination of cisplatin and gemcitabine prolongs survival by about 3 months in patients with locally advanced or metastatic cholangiocarcinoma. Few patients survive for more than 24 months. Although cholangiocarcinoma is generally considered to be a contraindication to liver transplantation because of rapid tumor recurrence, a 75% 5-year survival rate has been reported in patients with stage I and II cholangiocarcinoma undergoing chemoradiation and exploratory laparotomy followed by liver transplantation.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5).
respectively; and mutation of the palladin gene is reported to be common. In 5–10% of cases, pancreatic cancer occurs as part of several hereditary syndromes, including familial breast cancer (carriers of BRCA-2 have a 7% lifetime risk of pancreatic cancer), hereditary pancreatitis (PSS1 mutation), familial atypical multiple mole melanoma (p16/CDKN2A mutation), Peutz-Jeghers syndrome (STK11/LKB1 mutation), ataxia-telangiectasia, and hereditary nonpolyposis colorectal cancer. Polymorphisms of the genes for methylene tetrahydrofolate reductase and thymidylate synthase have been reported to be associated with pancreatic cancer. Neuroendocrine tumors account for 1–2% of pancreatic neoplasms and may be functional (producing gastrin, insulin, glucagon, vasoactive intestinal peptide, somatostatin, growth hormone–releasing hormone, adrenocorticotropic hormone, and others) or nonfunctional. Plasma chronogranin A levels are elevated in 88–100% of affected patients. Cystic neoplasms account for only 1% of pancreatic cancers, but they are important because they are often mistaken for pseudocysts. A cystic neoplasm should be suspected when a cystic lesion in the pancreas is found in the absence of a history of pancreatitis. At least 15% of all pancreatic cysts are neoplasms. Whereas serous cystadenomas (which account for 32–39% of cystic pancreatic neoplasms and also occur in patients with von Hippel-Lindau disease) are benign, mucinous cystic neoplasms (defined by the presence of ovarian stroma) (10–45%), intraductal papillary mucinous neoplasms (21–33%), solid pseudopapillary tumors (<5%), and cystic islet cell tumors (3–5%) may be malignant, although their prognoses are better than the prognosis of adenocarcinoma of the pancreas, unless the neoplasm is locally advanced.

► Clinical Findings

A. Symptoms and Signs

Pain is present in over 70% of cases and is often vague, diffuse, and located in the epigastrium or left upper quadrant when the lesion is in the tail. Radiation of pain into the back is common and sometimes predominates. Sitting up and leaning forward may afford some relief, and this usually indicates that the lesion has spread beyond the pancreas and is inoperable. Diarrhea, perhaps due to malabsorption, is an occasional early symptom. Migratory thrombophlebitis is a rare sign. Weight loss is a common but late finding and may be associated with depression. Occasionally a patient presents with acute pancreatitis in the absence of an alternative cause. Jaundice is usually due to biliary obstruction by a cancer in the pancreatic head. A palpable gallbladder is also indicative of obstruction by neoplasm (Courvoisier law), but there are frequent exceptions. A hard, fixed, occasionally tender mass may be present. In advanced cases, a hard periumbilical (Sister Joseph’s) nodule may be palpable.

B. Laboratory Findings

There may be mild anemia. Glycosuria, hyperglycemia, and impaired glucose tolerance or true diabetes mellitus are found in 10–20% of cases. The serum amylase or lipase level is occasionally elevated. Liver biochemical tests may suggest obstructive jaundice. Steatorrhea in the absence of jaundice is uncommon. Occult blood in the stool is suggestive of carcinoma of the ampulla of Vater (the combination of biliary obstruction and bleeding may give the stools a distinctive silver appearance). CA 19-9, with a sensitivity of 70% and a specificity of 87%, has not proved sensitive enough for early detection of pancreatic cancer; increased values are also found in acute and chronic pancreatitis and cholangitis.

C. Imaging

Multiphase thin-cut helical CT is generally the initial diagnostic procedure and detects a mass in over 80% of cases. CT identifies metastases, delineates the extent of the tumor, and allows for percutaneous FNA for cytologic studies and tumor markers. MRI is an alternative to CT. Ultrasonography is not reliable because of interference by intestinal gas. PET is a sensitive technique for detecting pancreatic cancer and metastases, but PET-CT is not a routine staging procedure. Selective celiac and superior mesenteric arteriography may demonstrate vessel invasion by tumor, a finding that would preclude attempts at surgical resection, but it is less widely used since the advent of multiphase helical CT. Endoscopic ultrasonography is more sensitive than CT for detecting pancreatic cancer and equivalent to CT for determining nodal involvement and resectability. A normal endoscopic ultrasonogram excludes pancreatic cancer. Endoscopic ultrasonography may also be used to guide FNA for tissue diagnosis, tumor markers, and DNA analysis. Endoscopic retrograde cholangiopancreatography (ERCP) may clarify an ambiguous CT scan or MRI study by delineating the pancreatic duct system or confirming an ampullary or biliary neoplasm. MRCP appears to be at least as sensitive as ERCP in diagnosing pancreatic cancer. In some centers, pancreatoscopy or intraductal ultrasonography can be used to evaluate filling defects in the pancreatic duct and assess resectability of intraductal papillary mucinous tumors. With obstruction of the splenic vein, splenomegaly or gastric varices are present, the latter delineated by endoscopy, endoscopic ultrasonography, or angiography.

Cystic neoplasms can be distinguished by their appearance on CT, endoscopic ultrasonography, and ERCP and features of the cyst fluid on gross and cytologic analysis. For example, serous cystadenomas may have a central scar or honeycomb appearance; mucinous cystadenomas are unilocular or multilocular and contain mucin-rich fluid with high carcinoembryonic antigen levels (>200 ng/mL) (200 mcg/L); and intraductal papillary mucinous neoplasms are associated with a dilated pancreatic duct and extrusion of gelatinous material from the ampulla.

► Staging

Staging of pancreatic cancer by the TNM classification includes the following definitions: Tis: carcinoma in situ; T1: tumor limited to the pancreas, 2 cm or less in greatest dimension; T2: tumor limited to the pancreas, more than
2 cm in greatest dimension; T3: tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery; T4, tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor); N1, regional lymph node metastasis; M1, distant metastasis.

**Treatment**

Abdominal exploration is usually necessary when cytologic diagnosis cannot be made or if resection is to be attempted, which includes about 30% of patients. In patients with a localized mass in the head of the pancreas and without jaundice, laparoscopy may detect tiny peritoneal or liver metastases and thereby avoid resection in 4–13% of patients. Radical pancreaticoduodenal (Whipple) resection is indicated for lesions strictly limited to the head of the pancreas, periampullary area, and duodenum (T1, N0, M0). Five-year survival rates are 20–25% in this group and as high as 40% in those with negative resection margins and without lymph node involvement. Preoperative endoscopic decompression of an obstructed bile duct is often achieved with a plastic stent or short metal stent but does not reduce operative mortality and is associated with complications. The best surgical results are achieved at centers that specialize in the multidisciplinary treatment of pancreatic cancer. Adjuvant or neoadjuvant chemotherapy with gemcitabine or fluorouracil (or both), possibly combined with irradiation, is of benefit (Table 39-4). Chemoradiotherapy downstages about 30% of patients with locally advanced disease to allow resection. When resection is not feasible, endoscopic stenting of the bile duct is performed to relieve jaundice. A plastic stent is generally placed if the patient’s anticipated survival is < 6 months (or surgery is planned). A metal stent is preferred when anticipated survival is 6 months or greater. Whether covered metal stents designed to prevent tumor ingrowth offer an advantage over uncovered stents is uncertain because covered stents are associated with higher rates of migration and acute cholecystitis due to occlusion of the cystic duct. Surgical biliary bypass may be considered in patients expected to survive at least 6 months. Surgical duodenal bypass may be considered in patients in whom duodenal obstruction is expected to develop later; alternatively, endoscopic placement of a self-expandable duodenal stent may be feasible. Chemoradiation may be used for palliation of unresectable cancer confined to the pancreas. Chemotherapy has been disappointing in metastatic pancreatic cancer, although improved response rates have been reported with the combination of oxaliplatin, irinotecan, fluorouracil, and leucovorin (FOLFIRINOX). The addition of erlotinib (an inhibitor of the EGFR receptor), capecitabine (an oral fluoropyrimidine), or a platinum agent may improve survival but also increases toxicity. The high rate of K-ras mutations in pancreatic cancer limits the benefit of erlotinib. Nucleoside cytidine analogues and topoisomerase inhibitors are under study. Celiac plexus nerve block (under CT or endoscopic ultrasound guidance) or thoracoscopic splanchnicectomy may improve pain control. Photodynamic therapy is under study.

Surgical resection is the treatment of choice for neuroendocrine tumors, when feasible. Metastatic disease may be controlled with long-acting somatostatin analogs, interferon, peptide-receptor radionuclide therapy, and chemoembolization. There is a growing consensus that asymptomatic incidental pancreatic cysts ≤ 2 cm are at low risk for harboring invasive carcinoma. The cysts may be monitored by imaging tests at 6- to 12-month intervals and every 3–6 months in those > 2 cm, with surgery or possibly endoscopic ultrasound-guided cyst ablation performed if a cyst enlarges or exceeds 2.5 cm.

Surgical resection is indicated for mucinous cystic neoplasms, symptomatic serous cystadenomas, solid pseudopapillary tumors (which have a 15% risk of malignant transformation), and cystic tumors > 2 cm in diameter that remain undefined after helical CT, endoscopic ultrasonography, and diagnostic aspiration. All intraductal papillary mucinous neoplasms of the main pancreatic duct should be resected, but those of branch ducts may be followed with serial imaging if they are asymptomatic and exhibit benign features (eg, diameter < 3 cm [some authorities recommend a diameter ≤ 1.5 cm], absence of nodules or a thick wall); most of the latter remain stable on follow-up, but the risk of pancreatic ductal carcinoma and of nonpancreatic cancers may also be increased in this group of patients. In the absence of locally advanced disease, survival is higher for malignant cystic neoplasms than for adenocarcinoma. Endoscopic resection or ablation, with temporary placement of a pancreatic duct stent, may be feasible for ampullary adenomas, but patients must be followed for recurrence.

**Prognosis**

Carcinoma of the pancreas, especially in the body or tail, has a poor prognosis; 80–85% of patients present with advanced unresectable disease, and reported 5-year survival rates range from 2% to 5%. Lesions of the ampulla have a better prognosis, with reported 5-year survival rates of 20–40% after resection; jaundice and lymph node involvement are adverse prognostic factors. In carefully selected patients, resection of cancer of the pancreatic head is feasible and results in reasonable survival. In persons with a family history of pancreatic cancer in at least two first-degree relatives, screening with endoscopic ultrasonography and helical CT or MRI/MRCP should be considered beginning at age 40–45 or 10 years before the age at which pancreatic cancer was diagnosed in a family member.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5).

**When to Refer**

All patients with carcinoma involving the pancreas and the periampullary area should be referred to a specialist.

**When to Admit**

Patients who require surgery and other interventions should be hospitalized.

**Alimentary Tract Cancers**

Kenneth R. McQuaid, MD
Robin K. Kelley, MD

---

**Esophageal Cancer**

- Progressive solid food dysphagia.
- Weight loss common.
- Endoscopy with biopsy establishes diagnosis.
Endoscopy with biopsy establishes the diagnosis of esophageal carcinoma with a high degree of reliability. In some cases, significant submucosal spread of the tumor may yield nondiagnostic mucosal biopsies. Repeated biopsy may be necessary.

**D. Upper Endoscopy**

Endoscopy with biopsy establishes the diagnosis of esophageal carcinoma with a high degree of reliability. In some cases, significant submucosal spread of the tumor may yield nondiagnostic mucosal biopsies. Repeated biopsy may be necessary.

**E. Staging**

After confirmation of the diagnosis of esophageal carcinoma, the stage of the disease should be determined since doing so influences the choice of therapy. Patients should undergo evaluation with CT of the chest and abdomen to look for evidence of pulmonary or hepatic metastases, lymphadenopathy, and local tumor extension. If there is no evidence of distant metastases or extensive local spread on CT, endoscopic ultrasonography with guided FNA biopsy of lymph nodes should be performed, which is superior to CT in demonstrating the level of local mediastinal extension and local lymph node involvement. PET with fluorodeoxyglucose or integrated PET-CT imaging is indicated to look for regional or distant spread in patients thought to have localized disease after other diagnostic studies. Bronchoscopy is sometimes required in esophageal cancers above the carina to exclude tracheobronchial extension. Laparoscopy to exclude occult peritoneal carcinomatosis should be considered in tumors at gastrointestinal junction.

**F. Treatment**

The approach to esophageal cancer depends on the tumor stage, patient preference and functional status, and the expertise of the surgeons, oncologists, gastroenterologists, and radiotherapists. There is no consensus about the optimal treatment approach. It is helpful, however, to classify patients into two general categories.

**A. Therapy for “Curable” Disease**

Superficial esophageal cancers confined to the epithelium (high-grade dysplasia or carcinoma in situ [Tis]), lamina propria (T1a), or submucosal (T1b) are increasingly recognized in endoscopic screening and surveillance programs. Esophagectomy achieves high cure rates for superficial tumors but is associated with mortality (2%) and morbidity. If performed by experienced physicians, endoscopic mucosal resection of superficial cancers (especially Tis and T1a) achieves equivalent long-term survival with less morbidity. For a full discussion of management options in superficial adenocarcinoma, see the section on Barrett Esophagus in Chapter 15.
1. Surgery with or without neoadjuvant chemoradiation therapy—There is debate over the optimal surgical approach for invasive (non-superficial) but potentially “curable” esophageal cancers (stage I, II, or IIIA). The procedure with the lowest morbidity is transhiatal esophagectomy with anastomosis of the stomach to the cervical esophagus; however, this approach does not involve sampling or removal of mediastinal lymph nodes. Alternatively, surgeons may perform en bloc transthoracic excision of the esophagus with extended dissection of lymph nodes in the mediastinum and upper abdomen. In a randomized controlled trial comparing these two approaches, en bloc resection was associated with higher perioperative morbidity but a nonsignificant trend toward improved 5-year survival (39% vs 27%). Transhiatal resection may be more appropriate for patients who are elderly or have comorbid illness, and en bloc resection more appropriate in younger or healthier patients with a better prognosis.

Patients with stage I tumors have high cure rates with surgery alone and do not require radiation or chemotherapy. If regional lymph node metastases have occurred (stages II and III), the rate of cure with surgery alone is reduced to <20%. Meta-analysis of trials comparing neoadjuvant (preoperative) therapy followed by surgery with surgery alone suggests a 13% absolute improvement in 2-year survival with combined therapy. A 2008 randomized phase III trial of surgery alone versus a combined modality approach with neoadjuvant chemoradiation followed by surgery also demonstrated a significant survival benefit, with 5-year survival of 39% in the combined modality group versus 16% for surgery alone. Therefore, preoperative (neoadjuvant) chemoradiation therapy is recommended for stage IIA, IIB, and III tumors in fit patients. The chemotheraphy regimens used with radiation include weekly carboplatin plus paclitaxel or two cycles of cisplatin plus 5-fluorouracil, based on the randomized phase III CROSS trial and CALGB 9781, respectively. Preoperative chemotheraphy without radiation is also appropriate for tumors of the gastroesophageal junction based on the randomized, multicenter, phase III MAGIC trial.

2. Chemotherapy plus radiation therapy without surgery—Combined treatment with chemotherapy and radiation therapy is superior to radiation therapy alone and has achieved long-term survival rates in up to 25% of patients. Chemoradiation therapy alone should be considered in patients with localized disease (stage I or IIIA) who are poor surgical candidates due to serious medical illness or poor functional status (Eastern Cooperative Oncology Group score > 2). Chemoradiation alone as definitive, nonsurgical therapy is more likely to achieve long-term disease-free survival in patients with squamous cell carcinoma than in patients with adenocarcinoma.

B. Therapy for Incurable Disease

More than half of patients have either locally extensive tumor spread (T4) that is unresectable or distant metastases (M1), stage IIIB and stage IV tumors. Surgery is not warranted in these patients. Since prolonged survival can be achieved in few patients, the primary goal is to provide relief from dysphagia and pain, optimize quality of life, and minimize treatment side effects. The optimal palliative approach depends on the presence or absence of metastatic disease, expected survival, patient preference, and local institutional experience. Many patients with advanced disease may prefer concerted efforts at pain relief and care directed at symptom management (see Chapter 5).

1. Radiation therapy, chemotherapy, and combined therapy—Combined radiation therapy and chemotherapy may achieve palliation in two-thirds of patients but is associated with significant side effects. It should be considered for patients with locally advanced tumors without distant metastases (stage IIIIB) who have good functional status and no significant medical problems, in whom prolonged survival may be achieved. Improvement in dysphagia occurs within 2–4 weeks in almost 90% of patients.

Combination chemotherapy may be considered in patients with metastatic disease who still have good functional status and expected survival of several months. Although there is no consensus on optimal therapy, three drug combinations are commonly used: (1) epirubicin or a taxane (docetaxel or paclitaxel), (2) cisplatin or oxaliplatin, and (3) a fluoropyrimidine (5-FU or capecitabine). For patients with poor functional status, single-agent therapy with a fluoropyrimidine, a taxane, or irinotecan may be used. In patients with metastatic distal esophageal and gastroesophageal junction adenocarcinomas positive for amplification of the HER-2 gene (approximately 15% of cases), addition of the monoclonal antibody trastuzumab to chemotherapy is associated with prolonged survival.

Radiation therapy alone may afford short-term relief of pain and dysphagia and may be suitable for patients with poor functional status or underlying medical problems. This can generally be performed in a short course over a few weeks or less, but may be complicated by temporary worsening of dysphagia and odynophagia. For patients with frank obstruction or near obstruction, local anti-tumor therapies may be preferred.

2. Local therapy—Patients with advanced esophageal cancer often have a poor functional and nutritional status with an average survival of <12 weeks from diagnosis. In patients with poor performance status, chemoradiation or radiation may be associated with greater toxicity than potential for long-term benefit. Rapid palliation of dysphagia may be achieved by peroral placement of permanent expandable wire stents, application of endoscopic laser therapy, or photodynamic therapy. Palliative feeding tube placement may be considered for hydration and nutrition in selected cases if the obstruction is not amenable or if it is refractory to stenting, radiation, or other local therapies. Although dysphagia and quality of life are improved significantly, patients can seldom eat normally. Stents are most commonly used because of their relative ease of placement, although the choice of treatment depends on available expertise and equipment. Complications of stents occur in 20–40% and include perforation, migration, and tumor ingrowth.
Patients with metastatic disease and obstructive tumors should be admitted. Patients with high-grade esophageal obstruction with palliative care are essential (see Chapter 5).

The overall 5-year survival rate of esophageal carcinoma is < 20%. Apart from distant metastasis (M1b), the two most important predictors of poor survival are adjacent mediastinal spread (T4) and lymph node involvement. Whereas cure may be achieved in patients with regional lymph node involvement (stages IIB and III), involvement of nodes outside the chest (M1a) is indicative of metastatic disease (stage IV) that is incurable. For those patients whose disease progresses despite chemotherapy, meticulous efforts at palliative care are essential (see Chapter 5).

When to Refer

- Patients should be referred to gastroenterologist for evaluation and staging (endoscopy with biopsy, endoscopic ultrasonography) and palliative endoscopic anti-tumor therapy (stent).
- Patients with metastatic disease and obstructive tumors not amenable or refractory to palliative radiation or stenting may require referral to an interventional radiologist, gastroenterologist, or surgeon for feeding tube placement.
- Patients with curable and resectable disease (stage IIB or IIIA) and those with locally advanced or metastatic disease should be referred to an oncologist for consideration of neoadjuvant chemoradiotherapy or palliative chemotherapy, respectively.

When to Admit

Patients with high-grade esophageal obstruction with inability to manage oral secretions or maintain hydration should be admitted.

Prognosis

The overall 5-year survival rate of esophageal carcinoma is < 20%. Apart from distant metastasis (M1b), the two most important predictors of poor survival are adjacent mediastinal spread (T4) and lymph node involvement. Whereas cure may be achieved in patients with regional lymph node involvement (stages IIB and III), involvement of nodes outside the chest (M1a) is indicative of metastatic disease (stage IV) that is incurable. For those patients whose disease progresses despite chemotherapy, meticulous efforts at palliative care are essential (see Chapter 5).

When to Refer

- Patients should be referred to gastroenterologist for evaluation and staging (endoscopy with biopsy, endoscopic ultrasonography) and palliative endoscopic anti-tumor therapy (stent).
- Patients with metastatic disease and obstructive tumors not amenable or refractory to palliative radiation or stenting may require referral to an interventional radiologist, gastroenterologist, or surgeon for feeding tube placement.
- Patients with curable and resectable disease (stage IIB or IIIA) and those with locally advanced or metastatic disease should be referred to an oncologist for consideration of neoadjuvant chemoradiotherapy or palliative chemotherapy, respectively.

When to Admit

Patients with high-grade esophageal obstruction with inability to manage oral secretions or maintain hydration should be admitted.

GASTRIC ADENOCARCINOMA

ESSENTiAlS Of DiA GiNoSiS

- Dyspeptic symptoms with weight loss in patients over age 40 years.
- Iron deficiency anemia: occult blood in stools.
- Abnormality detected on upper gastrointestinal series or endoscopy.

General Considerations

Gastric adenocarcinoma remains the second most common cause of cancer death worldwide. However, its incidence has declined rapidly over the last 70 years, especially in western countries, which may be attributable to changes in diet (more fresh foods and vegetables), food refrigeration (allowing more fresh foods and reduced salted, smoked, and preserved foods), reduced toxic environmental exposures, and a decline in Helicobacter pylori. The incidence of gastric cancer remains high (70/100,000) in Japan and many developing regions, including eastern Asia, Eastern Europe, Chile, Colombia, and Central America. In the United States, there are an estimated 21,500 new cases and 10,800 deaths/year. The incidence is higher in Latinos, African Americans, and Asian Americans.

There are two main histologic variants of gastric cancer: “intestinal-type” (which resembles intestinal cancers in forming glandular structures) and “diffuse” (which is poorly differentiated, has signet-ring cells, and lacks glandular formation). Although both types are declining in incidence, intestinal-type has had the most dramatic reduction. Intestinal-type is still more common (70–80%), occurs twice as often in men as women, primarily affects older people (mean age 63 years), and is more strongly associated with environmental factors. It is believed to arise through a gradual, multi-step progression from inflammation (most commonly due to H pylori), to atrophic gastritis, to intestinal metaplasia, and finally dysplasia or cancer. Chronic H pylori gastritis is the strong risk factor for gastric carcinoma, increasing the relative risk 3.5- to 20-fold. It is estimated that 60–90% of cases of gastric carcinomas may be attributable to H pylori. Other risk factors for
intestinal-type gastric cancer include pernicious anemia, a history of partial gastric resection more than 15 years previously, smoking, and diets that are high in nitrates or salt and low in vitamin C.

**Diffuse gastric cancer** accounts for 20–30% of gastric cancer. In contrast to intestinal-type cancer, it affects men and women equally, occurs more commonly in young people, is not as strongly related to *H pylori* infection, has a worse prognosis, and has not declined in incidence. Most diffuse gastric cancers are attributable to acquired or hereditary mutations in the genes regulating the E-cadherin cell adhesion protein. Familial diffuse gastric cancer accounts for 1–3% of gastric cancers. The cancer may arise at a young age, is often multifocal and infiltrating with signet ring cell histology, and confers poor prognosis. Many of these families have a germline mutation of E-cadherin CDH1, which is inherited in an autosomal dominant pattern and carries a > 60% lifetime risk of gastric cancer. Prophylactic gastrectomy should be considered in patients known to carry this mutation.

Most gastric cancers arise in the body and antrum. These may occur in a variety of morphologic types: (1) polypoid or fungating intraluminal masses; (2) ulcerating masses; (3) diffusely spreading (limitis plastica), in which the tumor spreads through the submucosa, resulting in a rigid, atonic stomach with thickened folds (prognosis dismal); and (4) superficially spreading or “early” gastric cancer—confined to the mucosa or submucosa (with or without lymph node metastases) and associated with a favorable prognosis.

In contrast to the dramatic decline in cancers of the distal stomach, a rise in incidence of tumors of the gastric cardia has been noted. These tumors have demographic and pathologic features that resemble Barrett-associated esophageal adenocarcinomas (see Esophageal Cancer).

#### Clinical Findings

**A. Symptoms and Signs**

Gastric carcinoma is generally asymptomatic until the disease is quite advanced. Symptoms are nonspecific and are determined in part by the location of the tumor. Dyspepsia, vague epigastric pain, anorexia, early satiety, and weight loss are the presenting symptoms in most patients. Patients may derive initial symptomatic relief from over-the-counter remedies, further delaying diagnosis. Ulcerating lesions can lead to acute gastrointestinal bleeding with hematemesis or melena. Pyloric obstruction results in postprandial vomiting. Lower esophageal obstruction causes progressive dysphagia. Physical examination is rarely helpful. A gastric mass is palpated in < 20% of patients. Signs of metastatic spread include a left supraclavicular lymph node (Virchow node), an umbilical nodule (Sister Mary Joseph nodule), a rigid rectal shelf (Blumer shelf), and ovarian metastases (Krukenberg tumor). Guaiac-positive stools may be detectable.

**B. Laboratory Findings**

Iron deficiency anemia due to chronic blood loss or anemia of chronic disease is common. Liver function test abnormalities, particularly elevation of alkaline phosphatase, may be present if there is metastatic liver spread. Other tumor markers are of no value.

**C. Endoscopy**

Upper endoscopy should be obtained in all patients over age 55 years with new onset of epigastric symptoms (dyspepsia) and in anyone with dyspepsia that is persistent or fails to respond to a short trial of antisecretory therapy. Endoscopy with biopsies of suspicious lesions is highly sensitive for detecting gastric carcinoma. It can be difficult to obtain adequate biopsy specimens in limitis plastica lesions.

**D. Imaging**

A barium upper gastrointestinal series is an acceptable alternative when endoscopy is not readily available but may not detect small or superficial lesions and cannot reliably distinguish benign from malignant ulcerations. Any abnormalities detected with this procedure require endoscopic confirmation.

Once a gastric cancer is diagnosed, preoperative evaluation with CT of chest and abdomen (including pelvis in females) and endoscopic ultrasonography is indicated to delineate the local extent of the primary tumor as well as nodal or distant metastases. PET or combined PET-CT imaging may be more sensitive than CT for detection of distant metastasis. Endoscopic ultrasonography is superior to CT in determining the depth of tumor penetration and is useful for evaluation of early gastric cancers that may be removed by endoscopic mucosal resection.

**Screening**

Because of its unproven efficacy and cost-effectiveness, screening for *H pylori* infection and treating it to prevent gastric cancer is not recommended for asymptomatic adults in the general population but may be considered in patients who have immigrated from regions with a high incidence of gastric cancer or who have a family history of gastric cancer. Because of the high incidence of gastric carcinoma in Japan, screening upper endoscopy is performed to detect early gastric carcinoma. Approximately 40% of tumors detected by screening are early, with a 5-year survival rate of almost 90%. Screening programs are not recommended in the United States.

**Staging**

Staging is defined according to the TNM system, in which T1 tumors involve the lamina propria (T1a) or submucosa (T1b), T2 invade the muscularis propria, T3 penetrate the serosa, and T4 invade adjacent structures. Lymph nodes are graded as N0 if there is no involvement, and N1, N2, or N3 if there are is involvement of 1–6, 7–15, or more than 15 regional nodes. M1 signifies the presence of metastatic disease.

**Differential Diagnosis**

Ulcerating gastric adenocarcinomas are distinguished from benign gastric ulcers by biopsies. Approximately 3% of
gastric ulcers initially believed to be benign later prove to be malignant. To exclude malignancy, all gastric ulcers identified at endoscopy should be biopsied. Ulcers that are suspicious for malignancy to the endoscopist or that have atypia or dysplasia on histologic examination warrant repeat endoscopy in 2–3 months to verify healing and exclude malignancy. Nonhealing ulcers should be considered for resection. Infiltrative carcinoma with thickened gastric folds must be distinguished from lymphoma and other hypertrophic gastropathies.

**Treatment**

**A. Curative Surgical Resection**

Surgical resection is the only therapy with curative potential. After preoperative staging, about two-thirds of patients will be found to have localized disease (ie, stages I–III). In Japan and in specialized centers in the United States, endoscopic mucosal resection is performed in selected patients with small (<1–2 cm), early (intramuscosal or T1aN0) gastric cancers after careful staging with endoscopic ultrasonography. Approximately 25% of patients undergoing surgery will be found to have locally unresectable tumors or peritoneal, hepatic, or distant lymph node metastases that are incurable. The remaining patients with confirmed localized disease should undergo radical surgical resection with curative intent. For adenocarcinoma localized to the distal two-thirds of the stomach, a subtotal distal gastrectomy should be performed. For proximal gastric cancer or diffusely infiltrating disease, total gastrectomy is necessary. Vitamin B12 supplementation is required postgastrectomy. Although lymph node dissection should be performed for curative resections, there has been ongoing debate about whether an extended (perigastric; D1), regional (D2), or distant ( porta hepatic and periaortic; D3) lymph node dissection is needed. A 2008 large Japanese trial found no difference in survival between patients treated with D2 and D3 (para-aortic) lymphadenectomy. Current NCCN treatment guidelines recommend regional (D2) node resection with 15 or more lymph nodes sampled. The role of prophylactic (neoadjuvant) or postoperative (adjuvant) chemotherapy or radiochemotherapy after curative resection is controversial. Recommended options include either adjuvant chemoradiation therapy (commonly 5-FU and leucovorin) or a perioperative chemotherapy regimen of epirubicin, 5-FU, and cisplatin (ECF) without radiation. Treatment of tumors arising in the gastroesophageal junction may be treated following algorithms for either gastric or esophageal primary tumors; multidisciplinary treatment decision-making involving the surgeon, radiation oncologist, and medical oncologist is imperative.

**B. Palliative Modalities**

Many patients will be found either preoperatively or at the time of surgical exploration to have advanced disease that is not amenable to “curative” surgery due to peritoneal or distant metastases or local invasion of other organs. In some of these cases, palliative resection of the tumor nonetheless may be indicated to alleviate pain, bleeding, or obstruction. For patients with unresectable disease, gastrojejunostomy may be indicated to prevent obstruction. Alternatively, unresected tumors may be treated with endoscopic laser or stent therapy, radiation therapy, or angiographic embolization to relieve bleeding or obstruction. Chemotherapy may be considered in patients with metastatic disease who still have good functional status and expected survival of several months. Multiple chemotherapy regimens have demonstrated activity in metastatic gastric adenocarcinoma. A combination of epirubicin, cisplatin, and 5-FU or a modification thereof is commonly used in first-line treatment for fit patients. A 2009 randomized, phase III study showed that addition of the biologic agent trastuzumab to standard chemotherapy prolonged survival in the subset (approximately 15%) of patients with advanced gastric adenocarcinomas harboring amplification of the EGFR-2 (HER-2). Trastuzumab is not recommended for combination with anthracyclines such as epirubicin, however, due to risk for cardiotoxicity.

**Prognosis**

The long-term survival of gastric carcinoma is <15%. However, 5-year survival in patients who undergo successful curative resection is over 45%. Survival is related to tumor stage, location, and histologic features. Stage I and stage II tumors resected for cure have a >50% long-term survival. Patients with stage III tumors have a poor prognosis (<20% long-term survival) and should be considered for enrollment in clinical trials. Tumors of the diffuse type have a worse prognosis than the intestinal type. Tumors of the proximal stomach (fundus and cardia) carry a far worse prognosis than distal lesions. Even with apparently localized disease, proximal tumors have a 5-year survival of <15%. For those whose disease progresses despite therapy, meticulous efforts at palliative care are essential (see Chapter 5).

**When to Refer**

- Patients with dysphagia, weight loss, protracted vomiting, iron-deficiency anemia, or new-onset of dyspepsia (especially if age 55 years or older or associated with other alarm symptoms) in whom gastric cancer is suspected should be referred to a gastroenterologist for endoscopic screening.
- Patients should be referred to a surgeon for attempt at curative resection in stage I, II, or III cancer as well as to an oncologist to evaluate for adjuvant or neoadjuvant chemotherapy (or both) or chemoradiotherapy.
- Patients who have undergone gastrectomy require consultation with a nutritionist due to propensity for malnutrition and complications, such as dumping syndrome, postoperatively.
- Patients with unresectable or metastatic disease should be referred to an oncologist for consideration of adjuvant chemotherapy or chemoradiotherapy after curative resection or palliative therapy.
GASTRIC LYMPHOMA

**General Considerations**

Gastric lymphomas may be primary (arising from the gastric mucosa) or may represent a site of secondary involvement in patients with nodal lymphomas. Distinguishing advanced primary gastric lymphoma with adjacent nodal spread from advanced nodal lymphoma with secondary gastric spread can be problematic. Because the prognosis and treatment of primary and secondary gastric lymphomas are entirely different, the distinction is important. Primary lymphoma is the second most common gastric malignancy, accounting for 3% of cancers. More than 95% of these are non-Hodgkin B cell lymphomas. Most primary gastric lymphomas are believed to arise from mucosa-associated lymphoid tissue (MALT). Primary gastric lymphomas comprise two main types: 60% are diffuse large B-cell lymphomas (previously called “high-grade” MALT lymphomas) and 40% are marginal zone B-cell lymphomas of the MALT-type (previously call “low-grade” MALT lymphoma).

Infection with *H pylori* is an important risk factor for the development of primary gastric lymphoma. Chronic infection with *H pylori* causes an intense lymphocytic inflammatory response that may lead to the development of lymphoid follicles. Over 90% of low-grade primary gastric MALT-type lymphomas are associated with *H pylori* infection. It is hypothesized that chronic antigenic stimulation may result in a monoclonal lymphoproliferation that may culminate in low-grade or high-grade lymphoma.

**Clinical Findings**

The clinical presentation and endoscopic appearance of gastric lymphoma are similar to those of adenocarcinoma. Most patients have abdominal pain, weight loss, or bleeding. Patients with diffuse large B-cell lymphoma are more likely to have systemic symptoms and advanced tumor stage. At endoscopy, lymphoma may appear as an ulcer, mass, or diffusely infiltrating lesion. The diagnosis is established with endoscopic biopsy. All patients should undergo staging with abdominal and chest CT. Endoscopic ultrasonography is the most sensitive test for determining the level of invasion and presence of perigastric lymphadenopathy.

**Treatment**

Nodal lymphomas with secondary gastrointestinal involvement usually present at an advanced stage with widely disseminated disease and are seldom curable. Their treatment is addressed in Chapter 13. Treatment of primary gastric lymphomas depends on the tumor histology, grade, and stage. Marginal B-cell lymphomas of the MALT type that are low-grade and localized to the stomach wall (stage I E) or perigastric lymph nodes (stage IIE) have an excellent prognosis. Endoscopic ultrasonography should be performed to accurately determine tumor stage. Patients with primary gastric MALT-lymphoma should be tested for *H pylori* infection and treated if positive. Complete lymphoma regression after successful *H pylori* eradication occurs in 75% of cases of stage I E and 55% with stage II, low-grade lymphoma. Remission may take as long as a year, and relapse occurs in 2% of

**When to Admit**

Patients with protracted vomiting, inability to maintain oral intake, or acute bleeding.

cases per year. Endoscopic surveillance after *H pylori* eradication is recommended every 6 months for 2 years to look for recurrence. Remission rates (22%) are much lower in patients whose tumors have an AP12-MALT1 gene translocation. Patients with localized marginal zone MALT-type lymphomas who either are not infected with *H pylori* or do not respond to eradication therapy may be treated with radiation therapy or rituximab, if not a candidate for radiation. Data from a 2010 study, however, suggest that many patients with minimal disease after successful *H pylori* eradication may be observed closely without further therapy. The long-term survival of low-grade MALT lymphoma for stage I is over 90% and for stage II is 35–65%. Patients with diffuse large cell (high-grade) lymphomas or disseminated MALT-type lymphomas should be treated with combination chemotherapy (eg, CHOP with rituximab). Because of a low risk of perforation with either radiation therapy or chemotherapy, surgical resection is no longer recommended.

**GASTRIC CARCINOID TUMORS**

Gastric carcinoids are rare neuroendocrine tumors that make up <1% of gastric neoplasms. They may occur sporadically or secondary to chronic hypergastrinemia that results in hyperplasia and transformation of enterochromaffin cells in the gastric fundus. Sporadic carcinoids account for 20% of gastric carcinoids. Most are solitary, over 2 cm in size, and have a strong propensity for metastatic spread. Most sporadic carcinoids already have carcinoid syndrome and hepatic or pulmonary metastatic involvement at initial presentation. Localized sporadic carcinoids should be treated with radical gastrectomy.

The majority of carcinoids caused by hypergastrinemia occur in association with either pernicious anemia (75%) or Zollinger-Ellison syndrome (5%). Carcinoids associated with Zollinger-Ellison syndrome occur almost exclusively in patients with MEN 1, in which loss of 11q13 has been reported. Carcinoids caused by hypergastrinemia tend to be multicentric, <1 cm in size, and have a low potential for metastatic spread or development of carcinoid syndrome. Small lesions may be successfully treated with endoscopic resection followed by periodic endoscopic surveillance. Antrectomy reduces serum gastrin levels and may lead to regression of small tumors. Patients with large or multiple carcinoids should undergo surgical tumor resection (see Carcinoid Tumors section).

**GASTROINTESTINAL MESENCHYMAL TUMORS**

Gastrointestinal mesenchymal tumors occur throughout the gastrointestinal tract, but approximately two-thirds occur in the stomach. These tumors (which include stromal tumors, leiomyomas, and schwannomas) derive from mesenchymal stem cells and have an epithelioid or spindle cell histologic pattern, resembling smooth muscle. The most common stromal tumors are gastrointestinal stromal tumors (“GISTs”), which appear to originate from interstitial cells of Cajal. GISTs occur throughout the gastrointestinal tract but most commonly in the stomach (50%) and small intestine (30%). About 85–90% of GISTs have mutations in KIT, a receptor tyrosine kinase that binds stem cell factor, or a homologous tyrosine kinase, platelet-derived growth factor alpha that lead to constitutive activation. Approximately 90% of stromal tumors stain positively for CD117 (part of the KIT protein). Other mesenchymal tumors such as leiomyomas, which derive from smooth muscle cells, stain negative for CD117. Mesenchymal tumors may be discovered incidentally on imaging studies or endoscopy or may cause symptoms, mainly obstruction by large tumors or acute or chronic bleeding due to central ulceration within the tumor. At endoscopy, they appear as a submucosal mass that may have central umbilication or ulceration. Endoscopic ultrasonography (possibly with guided FNA biopsy) is the optimal study for diagnosing mesenchymal tumors and distinguishing them from other submucosal lesions. While almost all GISTs have malignant potential, the risk of developing metastasis is related to the tumor size (>2 cm), location (small bowel is highest risk), and mitotic index (>5 mitoses per high-powered field); however, mitotic index can only be assessed after resection. It is difficult to distinguish with certainty benign from malignant (sarcoma) tumors before resection by endoscopic ultrasonographic appearance or FNA. In general, lesions that are smaller than 2 cm, have a smooth border, and have a homogeneous echo pattern on endoscopic ultrasonogram are more likely benign.

Surgery is recommended for all patients with tumors that are symptomatic, ≥2 cm, are increasing in size, or have an endoscopic ultrasonographic appearance suspicious for malignancy. PET-CT scan should be obtained prior to surgery to look for metastatic disease. The management of asymptomatic benign-appearing lesions ≤2 cm in size is problematic. Because of a low risk of malignancy, surgical resection should be considered in younger, otherwise healthy patients; however, other patients may be followed up with serial endoscopic ultrasonographic examinations or, in selected cases, endoscopic resections. (GIST tumors with high-risk features have a 50% 5-year survival rate after complete surgical resection.) Adjuvant therapy with the tyrosine kinase inhibitor imatinib delays recurrence and prolongs survival in patients with high-risk tumors. Three years of adjuvant imatinib is superior to 1 year, although optimal duration remains unknown. Metastatic tumors are aggressive and carry a poor prognosis. Imatinib induces disease control in up to 85% of patients with metastatic disease with a progression free-survival of 20–24 months and median overall survival of almost 5 years. Patients whose...
MALIGNANCIES OF THE SMALL INTESTINE

1. Adenocarcinoma

These are aggressive tumors that occur most commonly in the duodenum or proximal jejunum. The ampulla of Vater is the most common site of small bowel carcinoma, and the incidence of ampullary carcinoma is increased more than 200-fold in patients with familial adenomatous polyposis. Ampullary carcinoma may present with jaundice due to bile duct obstruction or bleeding. Surgical resection of early lesions is curative in up to 40% of patients. Periodic endoscopic surveillance to detect early ampullary neoplasms therefore is recommended in patients with this disorder. Nonampullary adenocarcinoma of the small intestine accounts for < 3% of all gastrointestinal cancers but one-third of small bowel cancers. Peak incidence is in the sixth decade. Most cases present with symptoms of obstruction, acute or chronic bleeding, or weight loss. The majority of small bowel cancers have already metastasized at the time of diagnosis. Resection is recommended for control of symptoms. The role of adjuvant therapy is unclear but is generally administered using chemotherapy agents active in colorectal cancer. The prognosis is poor with a 5-year overall survival of 20–30%. Patients with Crohn disease have an increased risk of small intestine adenocarcinoma, most commonly in the ileum, which may be difficult to distinguish from disease-related fibrous strictures. Small bowel adenocarcinoma in young patients or those with a family history of gastrointestinal adenocarcinomas should prompt screening for the Lynch syndrome.

2. Lymphoma

Gastrointestinal lymphomas may arise in the gastrointestinal tract or involve it secondarily with disseminated disease. In Western countries, primary gastrointestinal lymphomas account for 5% of lymphomas and 20% of small bowel malignancies. They occur most commonly in the distal small intestine. The majority are non-Hodgkin high-grade marginal zone B cell lymphomas. There is an increased incidence of small intestinal lymphomas in patients with AIDS, immunosuppressive therapy, and Crohn disease. T cell lymphomas may arise in patients with celiac sprue. In the Middle East, lymphomas may arise in the setting of immunoproliferative small intestinal disease. In this condition, there is diffuse lymphoplasmacytic infiltration with IgA-secreting B lymphocytes of the mucosa and submucosa that results in weight loss, diarrhea, and malabsorption, which may lead to lymphomatous transformation. A characteristic feature of the disease is the presence of α heavy chains in the serum in 70% produced by clones of IgA plasma cells. Other types of intestinal lymphomas include mantle cell and Burkitt.

Presenting symptoms or signs of primary lymphoma include abdominal pain, weight loss, nausea and vomiting, distention, anemia, and occult blood in the stool. Fevers are unusual. Protein-losing enteropathy may result in hypalbuminemia, but other signs of malabsorption are unusual. Barium radiography or CT enterography helps localize the site of the lesion. The diagnosis requires endoscopic, percutaneous, or laparoscopic biopsy. Imaging and bone marrow biopsy are required to determine stage.

Treatment depends on the tumor histologic grade and stage of disease. Resection of primary intestinal lymphoma, if feasible, is usually recommended. Even in cases of stage III or stage IV disease, surgical debulking may improve survival. In patients with limited disease (stage IE) in whom resection is performed, the role of adjuvant chemotherapy is unclear. Most patients with more extensive disease are treated with combination chemotherapy (eg, CHOP with rituximab) with or without radiation therapy.

3. Carcinoid Tumors

- Majority are asymptomatic and discovered incidentally at endoscopy or surgery.
- Carcinoid syndrome occurs in < 10%; hepatic metastases are generally present.
- Risk of metastasis related to tumor size and location.
General Considerations

Gastrointestinal carcinoids are slow growing neuroendocrine tumors that may arise anywhere in the gastrointestinal tract but most commonly occur in the small intestine (30%), rectum (12%), colon (8%), appendix (8%), and stomach (10–30%; see above). Carcinoids may contain a variety of hormones, including serotonin, somatostatin, gastrin, and substance P that may or may not be secreted, and usually display immunoreactivity to chromogranin A. Although many carcinoids behave in an indolent fashion, the overall 5-year survival rate for patients with carcinoids is 50%, suggesting that most are malignant. The risk of metastatic spread is closely related to tumor size and tumor location. Many small carcinoids are detected incidentally at endoscopy or autopsy. It is not possible by histologic examination to distinguish benign from malignant disease. The best indicator of prognosis is evidence of invasive growth and the presence of regional or distant metastasis.

Carcinoids account for one-third of small intestinal tumors. Small intestinal carcinoids most commonly arise in the ileum. Up to one-third are multicentric. Although 60% are < 2 cm in size, even these small carcinoids may metastasize. Almost all small intestinal carcinoids over 2 cm are associated with metastasis.

Appendiceal carcinoids are identified in 0.3% of appendectomies, usually as an incidental finding. Almost 80% of these tumors are < 1 cm in size, and 90% are < 2 cm. Rectal carcinoids are usually detected incidentally as submucosal nodules during proctoscopic examination. Rectal carcinoids < 1 cm and localized appendical carcinoids < 2 cm virtually never metastasize and are treated effectively with local excision or simple appendectomy. Tumors larger than 2 cm are associated with the development of metastasis in over 20% of appendical carcinoids and 10% of rectal carcinoids. Hence, in younger patients who are good candidates for surgery, a more extensive cancer resection operation is warranted.

Clinical Findings

A. Symptoms and Signs

Most smaller lesions (< 1–2 cm) are asymptomatic and difficult to detect by endoscopy or imaging studies. Through local extension or metastasis to mesenteric lymph nodes, carcinoids engender a fibroblastic reaction with contraction and kinking of the bowel or encasement of mesenteric vessels. Small intestinal carcinoids may present with abdominal pain, bowel obstruction, bleeding, or bowel infarction. Appendiceal and rectal carcinoids usually are small and asymptomatic but large lesions can cause bleeding, obstruction, or altered bowel habits. Carcinoid syndrome occurs in < 10% of patients. More than 90% of patients with carcinoid syndrome have hepatic metastases, usually from carcinoids of small bowel origin. About 10% of patients with carcinoid syndrome have primary bronchial or ovarian tumors without hepatic metastases. Carcinoid syndrome is caused by tumor secretion of hormonal mediators. The manifestations include facial flushing, edema of the head and neck (especially with bronchial carcinoid), abdominal cramps and diarrhea, bronchospasm, cardiac lesions (pulmonary or tricuspid stenosis or regurgitation in 10–30%), and telangiectases.

B. Laboratory Findings

Serum chromogranin A (CgA) is elevated in the majority of neuroendocrine tumors, although its sensitivity for small, localized carcinoid tumors is unknown. CgA is elevated in almost 90% of patients with advanced small bowel carcinoid. Urinary 5-hydroxyindoleacetic acid (5-HIAA) and platelet serotonin levels are also elevated in patients with metastatic carcinoid; however, these tests are less sensitive than CgA. There is increased urinary 5-HIAA in carcinoid syndrome; symptomatic patients usually excrete more than 25 mg of 5-HIAA per day in the urine. Ideally, all drugs should be withheld for several days prior to a 24-hour urine collection.

C. Imaging

Abdominal CT may demonstrate a mesenteric mass with tethering of the bowel, lymphadenopathy, and hepatic metastasis. Abdominal CT or enterography may reveal kinking of the bowel, but because the lesion is extra-luminal, the diagnosis may be overlooked for several years. Somatostatin receptor scintigraphy, which is positive in up to 90% of patients with metastatic carcinoid, is routinely used in staging. Most patients with carcinoid syndrome have liver metastasis on abdominal imaging.

Treatment

Small intestinal carcinoids are extremely indolent tumors with slow spread. Patients with disease confined to the small intestine should be treated with surgical excision, for which the cure rate exceeds 85%. In patients with resectable disease who have lymph node involvement, the 5-year disease-free survival is 80%; however, by 25 years, < 25% remain disease free. Even patients with hepatic metastases may have an indolent course with a median survival of 3 years. In patients with advanced disease, therapy historically has been deferred until the patient is symptomatic, although a 2009 phase III, randomized, placebo-controlled trial demonstrated that early initiation of somatostatin analog therapy delayed time to progression of hepatic metastases. Surgery should be directed toward palliation of obstructive symptoms.

In patients with carcinoid syndrome, resection of hepatic metastases may provide dramatic improvement. The somatostatin analog octreotide, 100–500 mcg subcutaneously three times daily or administered as a long-acting intramuscular depot formulation, inhibits hormone secretion from the carcinoid tumor. This results in dramatic relief of symptoms of carcinoid syndrome, including diarrhea or flushing, in 90% of patients for a median period of 1 year. Thereafter, many patients stop responding to octreotide. Hepatic artery occlusion, liver-directed debulking procedures, and chemotherapy may provide symptomatic improvement in some patients with hepatic metastases.
4. Small Intestine Sarcoma

Most small intestine sarcomas arise from stromal tumors (GISTs) that are positive for CD117; a minority arise from smooth muscle tumors (leiomyosarcomas) (see Gastrointestinal Mesenchymal Tumors above).

Kaposi sarcoma was at one time a common complication in AIDS, but the incidence is declining with highly active antiretroviral therapy (HAART). It is strongly associated with infection with human herpesvirus 8. Lesions may be present anywhere in the intestinal tract. Visceral involvement is usually associated with cutaneous disease. Most lesions are clinically silent; however, large lesions may be symptomatic. Interferon-α induces regression in up to one-third of patients who have a CD4 cell count of >200/μL. Widespread involvement may be best treated by systemic chemotherapy using combinations of vincristine, bleomycin, or doxorubicin, to which the tumor is very responsive.

Chambers AJ et al. The palliative benefit of aggressive surgical intervention for both hepatic and mesenteric metastases in up to one-third of patients who have a CD4 cell count of >200/μL. Widespread involvement may be best treated by systemic chemotherapy using combinations of vincristine, bleomycin, or doxorubicin, to which the tumor is very responsive.

Widespread involvement may be best treated by systemic chemotherapy using combinations of vincristine, bleomycin, or doxorubicin, to which the tumor is very responsive.

COLORECTAL CANCER

ESSENTIALS OF DIAGNOSIS

- Personal or family history of adenomatous polyps or colorectal cancer is important risk factors.
- Symptoms or signs depend on tumor location.
- Proximal colon: fecal occult blood, anemia.
- Distal colon: change in bowel habits, hematochezia.
- Diagnosis established with colonoscopy.

General Considerations

Colorectal cancer is the second leading cause of death due to malignancy in the United States. Colorectal cancer will develop in approximately 6% of Americans and 40% of those who will die of the disease. In 2010, there were an estimated 142,570 new cases and 51,370 deaths from colorectal cancer in the United States. Colorectal cancers are almost all adenocarcinomas, which tend to form bulky exophytic masses or annular constricting lesions. Slightly <50% of cancers are located distal to the splenic flexure (within the descending colon or rectosigmoid region).

The current belief is that the majority of colorectal cancers arise from malignant transformation of an adenomatous polyp (tubular, tubulovillous, or villous adenoma) or serrated polyp (hyperplastic polyp, traditional serrated adenoma, or sessile serrated adenoma). Polyps that are “advanced” (ie, polyps at least 1 cm in size, adenomas with villous features, or adenomas with high-grade dysplasia) are associated with a greater risk of cancer. Approximately 85% of sporadic colorectal cancers arise from adenomatous polyps and have loss of function of one or more tumor suppressor genes (eg, p53, APC, or DCC) due to a combination of spontaneous mutation of one allele combined with chromosomal instability and aneuploidy (abnormal DNA content) that leads to deletion and loss of heterozygosity of the other allele (eg, 5q, 17q, or 18p deletion). Activation of oncogenes such as K-ras and B-raf is present in a subset of colorectal cancers with prognostic and therapeutic implications discussed further below.

Approximately 10–20% of colorectal cancers arise from serrated polyps, most of which have hypermethylation of CpG-rich promoter regions that leads to inactivation of the DNA mismatch repair gene MLH1, resulting in microsatellite instability, and activation of mutations of the BRAF gene. Serrated colon cancers have distinct clinical and pathologic characteristics, including diploid DNA content, predominance in the proximal colon, poor differentiation, and more favorable prognosis.

Up to 5% of colorectal cancers are caused by inherited germline mutations resulting in polyposis syndromes (eg, familial adenomatous polyposis) or hereditary nonpolyposis colorectal cancer (HNPPC or Lynch syndrome). These conditions are discussed further in Chapter 15.

Risk Factors

A number of factors increase the risk of developing colorectal cancer. Recognition of these has impact on screening strategies. However, 75% of all cases occur in people with no known predisposing factors.

A. Age

The incidence of colorectal cancer rises sharply after age 45 years, and 90% of cases occur in persons over the age of 50 years.

B. Family History of Neoplasia

A family history of colorectal cancer is present in 20% of patients with colon cancer. Hereditary factors are believed...
to contribute to 20–30% of colorectal cancers; however, the genes responsible for most of these cases have not yet been identified. (See Chapter 15 for discussion of inherited polyposis syndromes.) Approximately 6% of the Ashkenazic Jewish population has a missense mutation in the APC gene (APC I1307K) that confers a modestly increased lifetime risk of developing colorectal cancer (OR 1.4–1.9) but phenotypically resembles sporadic colorectal cancer rather than familial adenomatous polyposis. Genetic screening is available, and patients harboring the mutation merit intensive screening.

A family history of colorectal cancer or adenomatous polyps is one of the most important risk factors for colorectal cancer. The risk of colon cancer is proportionate to the number and age of affected first-degree family members with colon neoplasia. People with one first-degree family member with colorectal cancer have an increased risk approximately two times that of the general-population; however, the risk is almost four times if the family member’s cancer was diagnosed at < 45 years of age. Patients with two first-degree relatives have a fourfold, or 25–30% lifetime, risk of developing colon cancer. First-degree relatives of patients with adenomatous polyps also have a twofold increased risk for colorectal neoplasia, especially if the polyp was large (> 10 mm) or detected before age 60 years.

C. Inflammatory Bowel Disease

The risk of adenocarcinoma of the colon begins to rise 7–10 years after disease onset in patients with ulcerative colitis and Crohn colitis. The cumulative risk approaches 5–10% after 20 years and 20% after 30 years. Chronic treatment with 5-ASA agents and folate is associated with a lower risk of cancer in patients with ulcerative colitis.

D. Dietary Factors and Chemoprevention

In epidemiologic studies, diets rich in fats and red meat are associated with an increased risk of colorectal adenomas and cancer, whereas diets high in fruits, vegetables, and fiber are associated with a decreased risk. However, prospective, randomized controlled trials failed to demonstrate a risk reduction in the recurrence of adenomatous polyps after treatment with a diet low in fat and high in fiber, fruits, and vegetables, or with fiber supplementation. Calcium carbonate (3 g/d) has been shown in large cohort studies as well as small prospective trials to yield a modest reduction in the relative risk of developing colorectal neoplasia; however, a prospective study of 36,000 women did not show a protective benefit of calcium (500 mg) and vitamin D (200 international units twice daily) in preventing colon cancer. Similarly, the risk of colon cancer is not decreased in persons taking folic acid supplements. The antioxidant vitamins A, C, E, and beta carotene also have not been shown to be of benefit in prospective controlled studies.

A US Preventive Services Task Force meta-analysis of cohort and case-control studies suggest that prolonged (> 6 years) regular use of aspirin (at least 325 mg twice weekly) or NSAIDs is associated with a 22–33% relative risk reduction in the incidence of colorectal cancer. Two prospective, blinded clinical trials have shown that daily low-dose aspirin (80–325 mg) reduces the number of recurrent adenomas at 1–3 years in patients with a history of colorectal adenomas or cancer; however, two large randomized controlled trials in the United States did not demonstrate a reduction in colorectal cancer incidence in patients taking low-dose aspirin over a 5–10 years. Because long-term aspirin use is associated with a low incidence of serious complications (gastrointestinal hemorrhage, stroke), the US Preventive Services Task Force concluded that it should not be prescribed as a chemopreventive agent in people without polyps or with small adenomas unless there are other medical indications. Long-term administration of low-dose aspirin may be considered in patients with a personal or family history of colorectal cancer or advanced adenomas; however, they do not obviate the need for colonoscopy screening and surveillance.

E. Other Factors

The incidence of colon adenocarcinoma is higher in blacks than in whites. It is unclear whether this is due to genetic or socioeconomic factors (eg, diet or reduced access to screening). Diabetes, metabolic syndrome, obesity, and cigarette smoking are associated with a modest increase in cancer risk.

Clinical Findings

A. Symptoms and Signs

Adenocarcinomas grow slowly and may be present for several years before symptoms appear. However, some asymptomatic tumors may be detected by the presence of fecal occult blood (see Colorectal Cancer Screening, below). Symptoms depend on the location of the carcinoma. Chronic blood loss from right-sided colonic cancers may cause iron deficiency anemia, manifested by fatigue and weakness. Obstruction, however, is uncommon because of the large diameter of the right colon and the liquid consistency of the fecal material. Lesions of the left colon often involve the bowel circumferentially. Because the left colon has a smaller diameter and the fecal matter is solid, obstructive symptoms may develop with colicky abdominal pain and a change in bowel habits. Constipation may alternate with periods of increased frequency and loose stools. The stool may be streaked with blood, though marked bleeding is unusual. With rectal cancers, patients note tenesmus, urgency, and recurrent hematochezia. Weight loss is uncommon. Physical examination is usually normal except in advanced disease. A mass may be palpable in the abdomen. The liver should be examined for hepatomegaly, suggesting metastatic spread. For cancers of the distal rectum, digital examination is necessary to determine whether there is extension into the anal sphincter or fixation, suggesting extension to the pelvic floor.

B. Laboratory Findings

A complete blood count is obtained to look for evidence of anemia. Elevated liver function tests, particularly the
The TNM system is the commonly used classification to stage colorectal cancer. Staging is important not only because it correlates with the patient’s long-term survival but also because it is used to determine which patients should receive adjuvant therapy.

**Differential Diagnosis**

The nonspecific symptoms of colon cancer may be confused with those of irritable bowel syndrome, diverticular disease, ischemic colitis, inflammatory bowel disease, infectious colitis, and hemorrhoids. Neoplasm must be excluded in any patient over age 40 years who reports a change in bowel habits or hematochezia or who has an unexplained iron deficiency anemia or occult blood in stool samples.

**Treatment**

**A. Surgery**

Resection of the primary colonic or rectal cancer is the treatment of choice for almost all patients who have resectable lesions and can tolerate general anesthesia. For colon cancer, multiple studies demonstrate that minimally invasive, laparoscopically assisted colectomy results in similar outcomes and rates of recurrence to open colectomy. Regional dissection of at least 12 lymph nodes should be performed to determine staging, which guides decisions about adjuvant therapy.

For rectal carcinoma, preoperative (neoadjuvant) chemoradiation with 5-FU is recommended in all node-positive tumors, and in T3 and greater tumors, due to increased risk of local recurrence. Neoadjuvant chemoradiation is discussed further below. After neoadjuvant therapy, the operative approach depends on the level of the tumor above the anal verge, the size and depth of penetration, and the patient’s overall condition. Clinical staging by endorectal ultrasound or MRI with endorectal coil is important in guiding the clinical approach. In carefully selected patients with small, mobile (< 4 cm), well-differentiated T1 or T2 rectal tumors that are < 8 cm from the anal verge and that appear on endosonography to be localized to the rectal wall, transanal excision may be performed. This approach avoids laparotomy and spares the rectum and anal sphincter, preserving normal bowel continence. All other patients will require either a low anterior resection with a colorectal anastomosis or an abdominoperineal resection with a colostomy, depending on how far above the anal verge the tumor is located and the extent of local tumor spread. Careful dissection of the entire mesorectum at the time of surgery has been shown to reduce local recurrence to 8%. With improvements in surgical stapling techniques, it is possible to perform low anterior resection provided there is a margin of at least 2 cm of normal tissue below the tumor. Although low anterior resections obviate a colostomy, they are associated with increased immediate postsurgical complications (leak, dehiscence, stricture) and defecatory complaints (increased stool frequency, defecatory problems, and incontinence).
With unresectable rectal cancer, the patient may be palliated with a diverting colostomy, laser fulguration, or placement of an expandable wire stent.

**B. Systemic Chemotherapy for Colon Cancer**

Chemotherapy and radiotherapy have been demonstrated to improve overall and tumor-free survival in selected patients with colorectal cancers depending on stage.

1. **Stage I**—Because of the excellent 5-year survival rate (90–100%), no adjuvant therapy is recommended.

2. **Stage II (node-negative disease)**—The expected 5-year survival rate is 80%. A survival benefit from adjuvant chemotherapy has not been demonstrated in most controlled trials for stage II colon cancer (see discussion for stage III disease). However, otherwise healthy patients with stage II disease that is at higher risk for recurrence (perforation, obstruction, T4 tumors, or fewer than 12 lymph nodes sampled) may benefit from adjuvant chemotherapy.

3. **Stage III (node-positive disease)**—With surgical resection alone, the expected 5-year survival rate is 30–50%. Postoperative adjuvant chemotherapy significantly increases disease-free survival as well as overall survival by up to 30% and is recommended for all fit patients. Large, well-designed studies of adjuvant therapy for stage III colon cancer reported a higher rate of disease-free survival at 5 years for patients treated with a combination of oxaliplatin, 5-FU, and leucovorin (FOLFOX) (73.3%) than with 5-FU and leucovorin (FL) alone (67.4%). The addition of oxaliplatin is associated with an increased incidence of diarrhea, myelosuppression, and peripheral sensory neuropathy, all of which generally are reversible. Based on these studies, FOLFOX currently is the preferred adjuvant therapy for most patients with stage III disease (see Table 39–11). The addition of a biologic agent (bevacizumab or cetuximab) to FOLFOX does not improve outcomes in the adjuvant setting.

4. **Stage IV (metastatic disease)**—Approximately 20% of patients have metastatic disease at the time of initial diagnosis, and another 30% eventually develop metastasis. A subset of these patients has limited disease that is potentially curable with surgical resection. Resection of isolated liver or lung metastases may result in long-term (over 5 years) survival in 35–55% of cases. For those with unresectable hepatic metastases, local ablative techniques (cryosurgery, radio-frequency or microwave coagulation, embolization, hepatic intra-arterial chemotherapy) may provide long-term tumor control. The majority of patients with metastatic disease do not have resectable (curable) disease. In the absence of other treatment, the median survival is only 6 months. The goals of therapy are to slow tumor progression while maintaining a reasonable quality of life for as long as possible. Currently, either FOLFOX (the addition of oxaliplatin to 5-FU and folinic acid) or FOLFIRI (the addition of irinotecan to 5-FU and folinic acid) is the preferred first-line treatment regimen for most patients with metastatic colorectal cancer, increasing median survival to 15–20 months. For convenience, oral capecitabine (instead of intravenous 5-FU and leucovorin) can be used in combination with oxaliplatin; however, combination with irinotecan should not be used due to increased toxicity (diarrhea). Addition of a biologic agent to combination chemotherapy improves response rates and overall survival and is recommended in the first-line of treatment in suitable patients. Bevacizumab is a monoclonal antibody targeting VEGF. Combination therapy with bevacizumab and FOLFOX or FOLFIRI prolongs mean survival 2–5 months compared with either regimen alone (see Table 39–11). Cetuximab and panitumumab are monoclonal antibodies targeting EGFR. Activating codon 12 and 13 K-ras gene mutations downstream of EGFR are present in approximately 35% of patients with metastatic colorectal cancer and are a biomarker for nonresponse to cetuximab and panitumumab, for which reason the use of these agents is restricted to patients with tumors wild-type for K-ras. In stage 4 patients with K-ras wild-type tumors, the addition of panitumumab or cetuximab to FOLFOX or FOLFIRI prolongs survival by approximately 4 months. Bevacizumab may cause serious side effects, including arterial thromboembolic events, bowel perforation, or serious bleeding, in up to 5% of patients. EGFR-targeted agents cause an acneiform rash in the majority of patients. Cetuximab is associated with anaphylaxis in a small subset.

When disease progresses with FOLFOX or FOLFIRI (often in conjunction with bevacizumab or an EGFR-targeted antibody), therapy is switched to the alternative regimen. Patients progressing with one regimen may respond to the alternative regimen, prolonging mean survival to > 20 months. A phase III study randomizing patients to receive either cetuximab or bevacizumab in addition to standard first-line chemotherapy (FOLFOX or FOLFIRI) is ongoing to determine whether one biologic agent is superior. The simultaneous combination of both classes of biologic agents (anti-EGFR and anti-VEGF) with chemotherapy has been associated with worse outcomes in multiple studies. This is a sobering finding that demonstrates the complexity of the signaling pathways involved. Single-agent, palliative therapy with cetuximab or panitumumab can benefit patients with K-ras wild-type tumors whose disease has progressed after first-line and second-line chemotherapies. Clinical trial participation should be considered for eligible patients whose tumors have progressed despite standard treatment, including 5-FU, oxaliplatin, irinotecan, an EGFR-inhibitor (if K-ras gene is wild-type), and bevacizumab.

Patients with metastatic colorectal cancer whose tumors harbor a mutation in the B-raf oncogene (approximately 8% in metastatic disease) have a significantly worse prognosis than patients whose tumors are wild-type for B-raf. Unlike activating K-ras mutations, randomized phase 3 data suggest potential benefit from cetuximab or panitumumab in combination with chemotherapy in patients whose tumors harbor an activating B-raf mutation (which almost never coexist with K-ras mutations).

**C. Adjuvant Therapy for Rectal Cancer**

Compared with colon cancer, rectal cancer has lower long-term survival rates and significantly higher rates of local recurrence.
tumor recurrence (25%) due to the difficulty of achieving adequate surgical resection margins. When initial imaging studies suggest stage I disease, surgery may be performed first. Combination therapy with 5-FU (as a radiation sensitizing agent) and radiation has been shown to improve the disease-free survival rate and to decrease pelvic recurrence and is recommended for all patients with stage II and stage III rectal cancers (see Table 39–11). Preoperative chemoradiation has been shown to be superior to postoperative chemoradiation and is recommended for patients with distal rectal cancers that are determined to be stage II or III by endorectal ultrasound or MRI. Following surgical resection with total mesorectal excision, 5-FU–based therapy is recommended for patients with similarly-staged colon cancers.

**Follow-Up after Surgery**

Patients who have undergone resections for cure are followed closely to look for evidence of symptomatic or asymptomatic tumor recurrence that may be amenable to curative resection in a small number of patients. The optimal cost-effective strategy is not clear. Two randomized trials reported that intense follow-up with yearly colonoscopy, abdominal CT, and chest radiography did not improve overall outcome compared with most standard follow-up protocols. Patients should be evaluated every 3–6 months for 3–5 years with history, physical examination, and CEA determinations. The NCCN recommends surveillance CT scans of chest, abdomen, and pelvis annually for the first 3 years post-resection in high-risk patients. Patients who had a complete preoperative colonoscopy should undergo another colonoscopy 1 year after surgical resection. Patients who did not undergo full colonoscopy preoperatively also should undergo colonoscopy within 3–6 months postoperatively to exclude other synchronous colorectal neoplasms. If a colonoscopy does not detect new adenomatous polyps 1 year postoperatively, surveillance colonoscopy should be performed every 3–5 years thereafter to look for metachronous polyps or cancer. Because of the high incidence of local tumor recurrence in patients with rectal cancer, proctoscopy surveillance of the low anterior resection anastomotic site may also be performed periodically. New onset of symptoms or a rising CEA warrants investigation with chest, abdominal, and pelvic CT to look for recurrent or metastatic disease that may be amenable to therapy. For patients with a rising CEA with unrevealing CT imaging, a PET scan is more sensitive for the detection of occult metastatic disease.

**Prognosis**

The stage of disease at presentation is the most important determinant of long-term survival: stage I, > 90%; stage II, 70–85%; stage III with fewer than four positive lymph nodes, 67%; stage III with more than four positive lymph nodes, 33%; and stage IV, 5–7%. For each stage, rectal cancers have a worse prognosis. For those patients whose disease progresses despite therapy, meticulous efforts at palliative care are essential (see Chapter 5).

**Screening for Colorectal Neoplasms**

Colorectal cancer is ideal for screening because it is a common disease that is fatal in almost 50% of cases yet is curable if detected at an earlier stage. Furthermore, most cases arise from benign adenomatous or serrated polyps that progress over many years to cancer, and removal of these polyps has been shown to prevent the majority of cancers. Colorectal cancer screening is endorsed by the US Preventive Services Task Force, the Agency for Health Care Policy and Research, the American Cancer Society, and every professional gastroenterology and colorectal surgery society. Although there is continued debate about the optimal cost-effective means of providing population screening, there is unanimous consent that screening of some kind should be offered to every patient over the age of 50 years. Several analyses suggest that screening is cost effective.

It is important for primary care providers to understand the relative merits of various options and to discuss them with their patients. Despite growing awareness of the importance of screening on the part of medical professionals and the public, < 50% of patients have undergone screening of any kind. Discussion and encouragement by the primary care provider are the most important factors in achieving patient compliance with screening programs.

Recommendations for screening from the US Multi-Society Task Force are listed in Table 39–5. Screening is recommended for all men and women aged 50 through 75 years of age who are at average risk for cancer. Some

1For recommendations for families with inherited polyposis syndromes or hereditary nonpolyposis colon cancer, see Chapter 15.
guidelines recommend screening for African Americans beginning at age 45. The potential for harm from screening must be weighed against the likelihood of benefit, especially in elderly patients with comorbid illnesses and shorter life expectancy. Although routine screening is not recommended in adults age 75, it may be considered on a case-by-case basis in adults age 76 through 85 years who have excellent health and functional status. Patients with first-degree relatives with colorectal neoplasms (cancer or adenomatous polyps) are at increased risk; earlier and more frequent screening is recommended (preferably with colonoscopy) for these individuals. Recommendations for screening in families with inherited cancer syndromes or inflammatory bowel disease are provided in Chapter 15. For patients at average risk for colorectal cancer, the recommendations of the Task Force are discussed below. Screening tests may be classified into two broad categories: stool-based tests and exams that visualize the structure of the colon by direct endoscopic inspection or radiographic imaging.

A. Stool-based Tests

1. Fecal occult blood test—Most colorectal cancers and some large adenomas result in increased chronic blood loss. A variety of tests for fecal occult blood are commercially available that have varying sensitivities and specificities for colorectal neoplasia. These include guaiac-based tests (Hemoccult I and II and Hemeoccult SENSA) that detect the pseudoperoxidase activity of heme or hemoglobin and fecal immunochemical tests (FITs) that detect human globin.

Guaiac-based tests have undergone the most extensive testing and currently have the greatest clinical use. For optimal detection, one specimen card must be prepared from three consecutive bowel movements. To reduce the likelihood of false-positive tests, patients should abstain from aspirin (in doses > 325 mg/d), NSAIDs, red meat, poultry, fish, and vegetables with peroxide activity (turnips, horseradish) for 72 hours. Vitamin C may cause a false-negative test. Slides should be developed within 7 days after preparation. The reported sensitivities of a single guaiac-based test for detection of colorectal cancer vary widely, but are lower for Hemeoccult II (35%) than Hemeoccult SENSA (65%). When fecal occult blood test is administered to the general population as part of a screening program, 2–6% of tests are positive. Of those with positive tests, 5–18% have colorectal cancer that is more likely to be at an earlier stage (stage I or II).

Several FITs are commercially available. These tests are highly specific for detecting human globin and therefore eliminate the need for pretest dietary restrictions. As with guaiac-based tests, sampling of three consecutive bowel movements is recommended. In clinical trials that compare FIT with guaiac-based tests, FIT had at least comparable sensitivity to Hemeoccult SENSA for detection of cancers (60–85%) with higher specificity. Because FITs are not affected by diet or medications and have superior accuracy, they are increasingly being substituted for guaiac-based tests despite a higher cost per test ($10–20).

The US Multi-Society Task Force emphasizes that colorectal cancer prevention should be the primary goal of screening. For that reason, the lower sensitivity of fecal occult blood tests for advanced neoplasia (cancer and advanced adenomatous polyps) makes them a less attractive choice for population-based screening than endoscopic or radiographic tests. Currently, fecal occult blood tests are most suitable in settings where health care resources are limited or in patients who desire a noninvasive method of screening. The Task Force recommends that tests with higher sensitivity for colorectal cancer (Hemeoccult SENSA or FIT) be used rather than less sensitive tests (Hemeoccult II). Regardless of which stool-based test is used, patients should understand that annual testing is required to achieve the maximum screening benefit and that a positive test will require evaluation by colonoscopy accompanied by removal of any polyps identified. If colonoscopy reveals no colorectal neoplasm, further screening for colorectal cancer can be deferred for 10 years. In a meta-analysis of four large, prospective, longitudinal studies, annual or biennial screening with Hemeoccult or Hemeoccult II reduced mortality from colorectal cancer by 25% among those who were compliant with regular testing. Long-term studies with more sensitive stool tests (Heme SENSA or FIT) have not been performed.

2. Multitarget DNA assay—A fecal DNA assay (Pre-Gen Plus) is available for screening for colorectal neoplasia. The test analyzes fecal DNA for 22 gene mutations and DNA integrity. The commercially available first-generation fecal DNA panel detected only one-half of cancers; however, a second-generation assay detected almost 90%. Although the Multi-Society Task Force concluded that fecal DNA is an acceptable option for colorectal cancer screening, this test is not yet practical for population-based screening due to its high cost and cumbersome requirements for stool collection and mailing.

B. Endoscopic Examinations of the Colon

1. Flexible sigmoidoscopy—Use of a 60-cm flexible sigmoidoscope permits visualization of the rectosigmoid and descending colon. It requires no sedation and in many centers is performed by a nurse specialist or physician’s assistant. Adenomatous polyps are identified in 10–20% and colorectal cancers in 1% of patients. Case-control studies suggest that screening sigmoidoscopy programs lead to a 60% reduction in colorectal cancer mortality. A 2010 randomized controlled trial in 170,000 participants in the United Kingdom comparing a one-time flexible sigmoidoscopy screening to usual care confirmed a 50% reduction in distal colorectal cancer incidence and 43% reduction in mortality after a median follow-up of 11 years. The risk of serious complications (perforation) associated with flexible sigmoidoscopy is < 1:10,000 patients.

The chief disadvantage of screening with flexible sigmoidoscopy is that it is does not examine the proximal colon. The prevalence of proximal versus distal neoplasia is higher in people over age 65 years of age, African Americans, and women. In men, approximately 50%
of advanced neoplasms (cancer, adenomas ≥ 1 cm in size, polyps with villous histology, or high-grade dysplasia) are located in the proximal colon, compared with 60–70% in women. The finding at sigmoidoscopy of an adenomatous polyp in the distal colon increases the likelihood at least twofold that an advanced neoplasm is present in the proximal colon. Therefore, patients found on screening sigmoidoscopy to have an adenomatous polyp of any size should subsequently undergo colonoscopy to evaluate the proximal colon. Using this strategy in men, it is estimated that screening sigmoidoscopy programs will detect approximately 65% of advanced colonic neoplasms. In women, however, sigmoidoscopy screening programs may fail to detect up to 65% of advanced neoplasia.

2. Colonoscopy—Colonoscopy permits examination of the entire colon. In addition to detecting early cancers, colonoscopy allows removal of adenomatous polyps by biopsy or polypectomy, which is believed to reduce the risk of subsequent cancer. Over the past decade, there has been a dramatic increase in screening colonoscopy and a similar decrease in screening sigmoidoscopy due to poor reimbursement and the perceived inferiority of sigmoidoscopy compared with colonoscopy. Colonoscopy requires aggressive bowel cleansing prior to the examination. To alleviate discomfort, intravenous sedation is used for most patients. The incidence of serious complications after colonoscopy (perforation, bleeding, cardiopulmonary events) is 0.1%. In asymptomatic individuals between 50 and 75 years of age undergoing screening colonoscopy, the prevalence of advanced neoplasia is 4–11% and of cancer is 0.1–1%.

Although colonoscopy is believed to be the most sensitive test for detecting adenomas and cancer, it is not infallible. In several studies, the rate of colorectal cancer within 3 years of a screening colonoscopy was 0.7–0.9%, ie, approximately 1 in 110 patients. This may be attributable to adenomatous polyps and early cancers that were overlooked during colonoscopy. Studies of back-to-back colonoscopies confirm that endoscopists overlook 6–12% of polyps > 1 cm and up to 25% of smaller adenomas. Polyps that are small, flat, or located behind folds are easily missed, especially if the bowel preparation is poor. Population-based case-control and cohort studies suggest that colonoscopy is associated with greater reduction in colorectal cancer incidence and mortality in the distal colon than the proximal colon. This may be attributable to incomplete examination of the proximal colon, and differences between the proximal and distal colon that include worse bowel preparation, suboptimal colonoscopic technique, and a higher prevalence of serrated polyps and flat adenomas. The latter are more common than previously recognized, are more likely to contain advanced pathology, and are more difficult to identify than raised (sessile or pedunculated) polyps. To optimize diagnostic accuracy as well as patient safety and comfort, colonoscopy should be performed after optimal bowel preparation by a well-trained endoscopist who spends sufficient time (at least 7 minutes) carefully examining the colon (especially the proximal colon) while withdrawing the endoscope.

C. Radiographic Examinations of the Colon

1. CT colonography—Using helical CT with computer-assisted image reconstruction, two- and three-dimensional views can be generated of the colon lumen that simulate the view of colonoscopy (virtual colonoscopy). CT colonography requires a similar bowel cleansing regimen as colonoscopy as well as insufflation of air into the colon through a rectal tube, which may be associated with discomfort. Nonetheless, this examination is performed rapidly and requires no sedation or intravenous contrast. It has minimal acute risk although there is controversy about potential long-term risks related to radiation exposure from CT examinations. Several large studies have compared the accuracy of virtual colonoscopy with colonoscopy for colorectal screening. Using current imaging software with multidetector helical scanners, the sensitivity is > 95% for the detection of cancer and > 84–92% for the detection of polyps ≥ 10 mm in size. The sensitivity for polyps 6–9 mm in size ranges from 57% to 84%; for polyps 5 mm or less, the sensitivity is extremely poor.

Patients undergoing screening with CT colonography should be managed appropriately. If no polyps are found, the interval for repeat screening examination is uncertain; however, 5 years may be reasonable. All patients with polyps ≥ 10 mm in size should be referred for colonoscopy with polypectomy because of the high prevalence (30%) of advanced pathology (cancer, high-grade dysplasia, or villous features) within these polyps. The optimal management of patients with polyps < 10 mm in size is controversial. The likelihood of advanced pathology in polyps 6–9 mm in size is 4–7% and in polyps 1–5 mm is < 2%. The US Multi-Society Task Force currently recommends that colonoscopy with polypectomy be offered to patients with one or more 6–9 mm polyps. Patients who refuse or who have increased risk of carcinoma should undergo surveillance CT colonography in 3–5 years. At the present time, there is no consensus on the management of patients with polyps < 6 mm; however, some radiologists choose not even to report these findings.

2. Barium enema—Double-contrast barium enema was previously used as a screening technique because it was widely available, relatively inexpensive, and safe. However, compared to CT colonography, it is more time consuming and difficult to perform, less comfortable, and less accurate. Although it continues to be included among recommended screening options, it has been supplanted by CT colonography, where available. A multicenter trial demonstrated that the sensitivity of barium enema is only 50% for polyps ≥ 1 cm and 55–85% for early-stage cancers when compared with colonoscopy. At present, barium enema may be recommended when screening of the entire colon is desired but expertise in CT colonography is unavailable and the patient is unable or unwilling to undergo colonoscopy.

When to Refer

- Patients with symptoms (change in bowel habits, hematochezia), signs (mass on abdominal examination or digital rectal examination [DRE]), or laboratory tests

- Patients undergoing screening with CT colonography should be managed appropriately. If no polyps are found, the interval for repeat screening examination is uncertain; however, 5 years may be reasonable. All patients with polyps ≥ 10 mm in size should be referred for colonoscopy with polypectomy because of the high prevalence (30%) of advanced pathology (cancer, high-grade dysplasia, or villous features) within these polyps. The optimal management of patients with polyps < 10 mm in size is controversial. The likelihood of advanced pathology in polyps 6–9 mm in size is 4–7% and in polyps 1–5 mm is < 2%. The US Multi-Society Task Force currently recommends that colonoscopy with polypectomy be offered to patients with one or more 6–9 mm polyps. Patients who refuse or who have increased risk of carcinoma should undergo surveillance CT colonography in 3–5 years. At the present time, there is no consensus on the management of patients with polyps < 6 mm; however, some radiologists choose not even to report these findings.

- Patients with symptoms (change in bowel habits, hematochezia), signs (mass on abdominal examination or digital rectal examination [DRE]), or laboratory tests
(iron deficiency anemia) suggestive of colorectal neoplasm should be referred for colonoscopy.

- Patients with suspected cancer or adenomatous polyps of any size should be referred for colonoscopy.

- Virtually all patients with proven colorectal cancer should be referred to a surgeon for resection. Patients with clinical stage T3 or node-positive rectal tumors (or both) also should be referred to an oncologist preoperatively for neoadjuvant therapy. Patients with stage III or IV colorectal tumors should be referred to an oncologist.

**When to Admit**

- Patients with complications of colorectal cancer (obstruction, acute bleeding) requiring urgent evaluation and intervention.

- Patients with severe complications of chemotherapy.

- Patients with advanced metastatic disease requiring palliative care.

**CARCINOMA OF THE ANUS**

The anal canal is lined from its proximal to distal extent by columnar, transitional and non-keratinized squamous epithelium, which merges at the anal verge with the keratinized perianal skin. Tumors arising from the mucosa of the anal canal are relatively rare, comprising only 1–2% of all cancers of the anus and large intestine. Squamous cancers typically arise from the abnormal lining of the anal canal, which merges at the anal verge with the keratinized perianal skin. Tumors arising from the mucosa of the anal canal are relatively rare, comprising only 1–2% of all cancers of the anus and large intestine. Squamous cancers typically arise from the abnormal lining of the anal canal, which merges at the anal verge with the keratinized perianal skin. It is important to recognize the importance of serrated polyps. Gastroenterology. 2010 Nov;139(5):1444–7. [PMID: 20875785]
Prostatic cancer is the most common noncutaneous cancer detected in American men and the second leading cause of cancer-related death. In the United States, over 241,000 new cases of prostate cancer are diagnosed annually, and about 28,000 deaths result. However, the clinical incidence of the disease does not match the prevalence noted at autopsy, where more than 40% of men over 50 years of age are found to have prostatic carcinoma. Most such occult cancers are small and contained within the prostate gland; few are associated with regional or distant disease. The incidence of prostatic cancer increases with age. Whereas 30% of men aged 60–69 years will have the disease, autopsy incidence increases to 67% in men aged 80–89 years. Although the global prevalence of prostatic cancer at autopsy is relatively consistent, the clinical incidence varies considerably (high in North America and European countries, intermediate in South America, and low in the Far East), suggesting that environmental or dietary differences among populations may be important for prostatic cancer growth. A 50-year-old American man has a lifetime risk of 40% for latent cancer, 16% for developing clinically apparent cancer, and a 2.9% risk of death due to prostatic cancer. Blacks, men with a family history of prostatic cancer, and those with a history of high dietary fat intake are at increased risk for developing prostate cancer.

Clinical Findings

A. Symptoms and Signs

Prostate cancer may manifest as focal nodules or areas of induration within the prostate at the time of DRE. However, currently most prostate cancers are associated with palpably normal prostates and are detected solely on the basis of elevations in serum PSA.

Patients rarely present with signs of urinary retention or neurologic symptoms as a result of epidural metastases and cord compression. Obstructive voiding symptoms are most often due to benign prostatic hyperplasia, which occurs in the same age group. Nevertheless, large or locally extensive prostatic cancers can cause obstructive voiding symptoms while lymph node metastases can lead to lower extremity lymphedema. As the axial skeleton is the most common site of metastases, patients may present with back pain or pathologic fractures.

B. Laboratory Findings

1. Serum tumor markers—PSA is a glycoprotein produced only by cells, either benign or malignant, of the prostate gland. The serum level is typically low and correlates with the volume of both benign and malignant prostate tissue. Measurement of serum PSA is useful in detecting and staging prostate cancer, monitoring response to treatment, and detecting recurrence before it becomes clinically evident. As a screening test, PSA will be elevated in 10–15% of men. Approximately 18–30% of men with intermediate degrees of elevation (4.1–10 ng/mL) will be found to have prostate cancer. Between 50% and 70% of those with elevations >10 ng/mL will have prostate cancer. Patients with intermediate levels of PSA usually have localized and therefore potentially curable cancers. It should be remembered that approximately 20% of patients...
who undergo radical prostatectomy for localized prostate cancer have normal levels of PSA.

In untreated patients with prostate cancer, the level of PSA correlates with the volume and stage of the disease. Whereas most organ-confined cancers are associated with PSA levels <10 ng/mL, advanced disease (seminal vesicle invasion, lymph node involvement, or occult distant metastases) is more common in patients with PSA levels in excess of 40 ng/mL. Approximately 98% of patients with metastatic prostate cancer will have elevated PSA. However, there are rare cancers that are localized despite substantial elevations in PSA. Therefore, initial treatment decisions cannot be made on the basis of PSA testing alone. A rising PSA after therapy is usually consistent with progressive disease, either locally recurrent or metastatic.

2. Miscellaneous laboratory testing—Patients in urinary retention or those with ureteral obstruction due to loco-regionally advanced prostate cancers may present with elevations in blood urea nitrogen or creatinine. Patients with bony metastases may have elevations in alkaline phosphatase or hypercalcemia. Laboratory and clinical evidence of disseminated intravascular coagulation can occur in patients with advanced prostate cancers.

3. Prostate biopsy—Transrectal ultrasound-guided biopsy is the standard method for detection of prostate cancer. The use of a spring-loaded, 18-gauge biopsy needle has allowed transrectal biopsy to be performed with minimal patient discomfort and morbidity. Local anesthesia is routinely used and increases the tolerability of the procedure. The specimen preserves glandular architecture and permits accurate grading. Prostate biopsy specimens are taken from the apex, mid-portion, and base in men who have an abnormal DRE or an elevated serum PSA, or both. Extended-pattern biopsies, including a total of at least ten biopsies, are associated with improved cancer detection and risk stratification of patients with newly diagnosed disease. Patients with abnormalities of the seminal vesicles can have these structures specifically biopsied to identify local tumor invasion.

C. Imaging

Transrectal ultrasonography has primarily been used for the staging of prostate carcinomas, where tumors typically appear as hypoechoic areas. In addition, transrectal ultrasound-guided, rather than digitally-guided, biopsy of the prostate is a more accurate way to evaluate suspicious lesions. Use of imaging should be tailored to the likelihood of advanced disease in newly diagnosed cases. Asymptomatic patients with well-differentiated to moderately differentiated cancers, thought to be localized to the prostate on DRE and transurethral ultrasound and associated with modest elevations of PSA (ie, < 10 ng/mL), need no further imaging.

MRI allows for evaluation of the prostate as well as regional lymph nodes. The positive predictive value for detection of both capsular penetration and seminal vesicle invasion is similar for transrectal ultrasound and MRI. CT plays little role because of its inability to accurately identify or stage prostate cancers, but it can be used to detect regional lymphatic metastases and intra-abdominal metastases.

Radionuclide bone scan is superior to conventional plain skeletal radiographs in detecting bony metastases. Most prostate cancer metastases are multiple and most commonly localized to the axial skeleton. Men with more advanced local lesions, symptoms of metastases (eg, bone pain), high-grade disease, or elevations in PSA > 20 ng/mL should undergo radionuclide bone scan. Because of the high frequency of abnormal scans in patients in this age group resulting from degenerative joint disease, plain films are often necessary in evaluating patients with indeterminate findings on bone scan. Cross-sectional imaging either by CT or MRI is usually indicated only in those patients in the latter group who have negative bone scans in an attempt to detect lymph node metastases. Patients found to have enlarged pelvic lymph nodes are candidates for FNA.

Intravenous urography and cystoscopy are not routinely needed to evaluate patients with prostate cancer. Despite application of modern, sophisticated techniques, understaging of prostate cancer occurs in at least 20% of patients.

Screening for Prostate Cancer

Whether screening for prostate cancer results in a decrease in mortality rates due to the disease is the subject of much debate. The screening tests currently available include DRE, PSA testing, and transrectal ultrasound. Depending on the patient population being evaluated, detection rates using DRE alone vary from 1.5% to 7%. Unfortunately, most cancers detected in this manner are advanced (stage T3 or greater). Transrectal ultrasound should not be used as a first-line screening tool because of its expense, low specificity (and therefore high biopsy rate), and minimal improvement in detection rate when compared with the combined use of DRE and PSA testing.

PSA testing increases the detection rate of prostate cancers compared with DRE. Approximately 2–2.5% of men older than 50 years of age will be found to have prostate cancer using PSA testing compared with a rate of approximately 1.5% using DRE alone. PSA is not specific for cancer, and there is considerable overlap of values between men with benign prostate hyperplasia and those with prostate cancers. The sensitivity, specificity, and positive predictive value of PSA and DRE are listed in Table 39–6. PSA-detected cancers are more likely to be localized compared with those detected by DRE alone. The Prostate Cancer Prevention Trial provided data demonstrating a significant risk of prostate cancer even in men with PSA less than 4.0 ng/mL (Table 39–7) and a web-based calculator has been developed to estimate the risk of harboring both cancer and high-grade prostate cancer (http://deb.uthscsa.edu/URORiskCalc/Pages/uroriskcalc.jsp).

To improve the performance of PSA as a screening test, several investigators have developed alternative methods for its use. These include establishment of age- and race-specific reference ranges, measurement of free serum and protein-bound levels of PSA (percent free
Two large, randomized trials question the benefit of screening men for prostate cancer. In the US Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial, no mortality benefit was observed after combined screening with PSA testing and digital rectal examination during follow-up of 13 years. Although screening resulted in a 12% increase in prostate cancer detection, the cancer-specific mortality rate was similar in the screening and control arms (3.7 and 3.4 deaths per 10,000 person-years, respectively). Similarly in the European Randomized Study of Screening for Prostate Cancer (ERSPC) trial, the benefit of PSA screening was minimal with a 20% relative reduction in death rate from prostate at follow-up of 9 years, with an absolute reduction of 7 prostate cancer deaths per 10,000 men screened. A subset of these patients from Göteborg, Sweden, in an independently designed and initiated population-based screening trial, was analyzed separately. During a median follow-up of 14 years, the absolute risk reduction of death from prostate cancer in the screening group was 40% and the relative risk of prostate-cancer death in the attendees of screening was 0.44. Based on these data, the US Preventive Services Task Force recommended against PSA-based screening for prostate cancer in asymptomatic men (grade D recommendation). Criticisms of the negative PLCO study include use of a relatively high PSA threshold (4 ng/mL), significant screening of men in the 3 years prior to enrolling in the trial (44%), and significant number of men in the control arm undergoing screening during the trial (> 50%).

### Staging

The majority of prostate cancers are adenocarcinomas. Most arise in the periphery of the prostate (peripheral zone), though a small percentage arise in the central (5–10%) and transition zones (20%) of the gland. Pathologists utilize the Gleason grading system whereby a “primary” grade is applied to the architectural pattern of malignant glands occupying the largest area of the specimen and a “secondary” pattern is assigned to the next largest area of cancer. Grading is based on architectural rather than histologic criteria, and five “grades” are possible (Figure 39–3). Adding the score of the primary and secondary patterns (grades) gives a Gleason score. Grade correlates with tumor volume, pathologic stage, and prognosis (Figure 39–4).

### Treatment

#### A. Localized Disease

The optimal treatment for patients with clinically localized prostate cancers remains controversial. Patients need to be advised of all treatment options, including active surveillance, with the specific benefits, risks, and limitations. Currently, treatment decisions are made based on tumor grade and stage as well as the age and health of the patient. Although selected patients may be candidates for surveillance based on age or health and evidence of small-volume or well-differentiated cancers, most men with an anticipated life expectancy in excess of 10 years should be
considered for treatment. Both radiation therapy and radical prostatectomy result in acceptable levels of local control. A large, prospective, randomized trial compared surveillance with radical prostatectomy in 695 men with clinically localized and well- differentiated to moderately differentiated tumors for a median of 12.8 years. Radical prostatectomy significantly reduced disease-specific mortality, overall mortality, and risks of metastasis and local progression. The relative reduction in the risk of death at 15 years was 0.62 in the prostatectomy group, with the number needed to treat to avert one death of 15; the benefit was confined to men younger than 65 years of age. This trial accrued patients in Sweden between 1989 and 1999, thus likely including patients with greater cancer burden compared with that in patients currently diagnosed using PSA screening. Nevertheless, the survival benefit in the trials was still observed in men with low-risk prostate cancer.
B. Radical Prostatectomy

During radical prostatectomy, the seminal vesicles, prostate, and ampullae of the vas deferens are removed. Refinements in technique have allowed preservation of urinary continence in most patients and erectile function in selected patients. Radical prostatectomy can be performed via open retropubic, transperineal, or laparoscopic (with or without robotic assistance) surgery. Local recurrence is uncommon after radical prostatectomy, and the incidence is related to pathologic stage. Organ-confined...
Radiation can be delivered by a variety of techniques including use of external beam radiotherapy and transperineal implantation of radioisotopes. Morbidity is limited, and the survival of patients with localized cancers (T1, T2, and selected T3) approaches 65% at 10 years. As with surgery, the likelihood of local failure correlates with technique and tumor characteristics. The likelihood of a positive prostate biopsy more than 18 months after radiation varies between 20% and 60%. Patients with local recurrence are at an increased risk of cancer progression and cancer death compared with those who have negative biopsies. Ambiguous target definitions, inadequate radiation doses, and understaging of the tumor may be responsible for the failure noted in some series. Newer techniques of radiation (implantation, conformal therapy using three-dimensional reconstruction of CT-based tumor volumes, heavy particle, charged particle, and heavy charged particle) may improve local control rates. Three-dimensional conformal radiation delivers a higher dose because of improved targeting and appears to be associated with greater efficacy as well as lower likelihood of adverse side effects compared with previous techniques. As a result of improvements in imaging, most cancers rarely recur; however, cancers with adverse pathologic features (capsular penetration, seminal vesicle invasion) are associated with higher local (10–25%) and distant (20–50%) relapse rates.

Ideal candidates for prostatectomy include healthy patients with stages T1 and T2 prostate cancers. Patients with advanced local tumors (T4) or lymph node metastases are rarely candidates for prostatectomy alone, although surgery is sometimes used in combination with hormonal therapy and postoperative radiation therapy for select high-risk patients.

Patients with advanced pathologic stage or positive surgical margins are at an increased risk for local and distant tumor relapse. Such patients are candidates for adjuvant therapy (radiation for positive margins or androgen deprivation for lymph node metastases). Two randomized clinical trials (EORTC 22911 and SWOG 8794) have demonstrated improved progression-free and metastasis-free survival with early radiotherapy in these men, and subsequent analysis of SWOG 8794 showed improved overall survival in men receiving adjuvant radiation therapy. Evidence suggests that salvage radiotherapy after radical prostatectomy, within 2 years of PSA relapse, increases prostate cancer-specific survival in men with shorter PSA doubling time (< 6 months).
notably transrectal ultrasound, there has been a resurgence of interest in brachytherapy—the implantation of permanent or temporary radioactive sources (palladium, iodine, or iridium) into the prostate. Brachytherapy can be combined with external beam radiation in patients with higher-grade or higher-volume disease or as monotherapy in those with low-grade or low-volume malignancies. The PSA may rise after brachytherapy because of prostate inflammation and necrosis. This transient elevation (PSA bounce) should not be mistaken for recurrence and may occur up to 20 months after treatment.

D. Surveillance

A beneficial impact of treating localized prostate cancer with respect to survival has not been conclusively demonstrated. Therefore, surveillance alone may be an appropriate form of management for selected patients with prostate cancer. Patients included in observational series are typically older with small volume, well-differentiated cancers. Many men with prostate cancer may be candidates for surveillance due to the significant migration to lower stage as well as lower grade, resulting from screening for prostate cancer using PSA testing. Depending on the age and health of the patient, some of these very low-volume, low-grade cancers may never become clinically relevant and can be monitored with serial PSA levels, rectal examinations, and periodic prostate biopsies to assess grade and extent of tumor. The goal of surveillance is to avoid treatment in men who never experience disease progression while recognizing and effectively treating men with evidence of progression. End points for intervention in patients on surveillance, particularly PSA changes, have not been clearly defined and surveillance regimens remain investigational.

E. Cryosurgery

Cryosurgery is a technique whereby liquid nitrogen is circulated through small hollow-core needles inserted into the prostate under ultrasound guidance. The freezing process results in tissue destruction. There has been a resurgence of interest in less invasive forms of therapy for localized prostate cancer as well as several recent technical innovations, including improved percutaneous techniques, expertise in transrectal ultrasound, improved cryotechnology, and better understanding of cryobiology. The positive biopsy rate after cryoablative ranges between 7% and 23%.

F. Locally and Regionally Advanced Disease

Prostate cancers associated with minimal degrees of capsular penetration are candidates for standard irradiation or surgery. Those with locally extensive cancers, including those with seminal vesicle and bladder neck invasion, are at increased risk for both local and distant relapse despite conventional therapy. Currently, a variety of investigational regimens are being tested in an effort to improve cancer outcomes in such patients. Combination therapy (androgen deprivation combined with surgery or irradiation), newer forms of irradiation, and hormonal therapy alone are being tested, as is neoadjuvant and adjuvant chemotherapy. Neoadjuvant and adjuvant androgen deprivation therapy combined with external beam radiation therapy have demonstrated improved survival compared with external beam radiation therapy alone.

G. Metastatic Disease

Since death due to prostate carcinoma is almost invariably the result of failure to control metastatic disease, research has emphasized efforts to improve control of distant disease. It is well known that most prostate carcinomas are hormone dependent and approximately 70–80% of men with metastatic prostate carcinoma will respond to various forms of androgen deprivation. Androgen deprivation may be affected at several levels along the pituitary–gonadal axis using a variety of methods or agents (Table 39–8). Use of luteinizing hormone-releasing hormone (LHRH) agonists (leuprolide, goserelin) achieves androgen deprivation without orchietomy or administration of diethylstilbestrol and is currently the most common method of reducing testosterone levels. A single LHRH antagonist (degarelix) is FDA approved and has no short-term testosterone “flare” associated with LHRH agonists. Because of its rapid onset of action, ketoconazole should be considered in patients with advanced prostate cancer who present with spinal cord compression, bilateral ureteral obstruction, or disseminated intravascular coagulation. Although testosterone is the major circulating androgen, the adrenal gland secretes the androgens dehydroepiandrosterone, dehydroepiandrosterone sulfate, and androstenedione. Some investigators believe that suppressing both testicular and adrenal androgens allows for a better initial and longer response than methods that only inhibit production of testicular androgens. Complete androgen blockade can be achieved by combining an antiandrogen with use of an LHRH agonist/antagonist or orchietomy. Nonsteroidal antiandrogen agents appear to act by competitively binding the receptor for dihydrotestosterone, the intracellular androgen responsible for prostate cell growth and development. A meta-analysis of trials comparing the use of either an LHRH agonist/orchietomy alone with the use of either in combination with an antiandrogen agent shows little benefit of combination therapy. However, patients at risk for disease-related symptoms (bone pain, obstructive voiding symptoms) due to the initial elevation of serum testosterone that accompanies the use of an LHRH agonist should receive antiandrogens initially. Bisphosphonates can prevent osteoporosis associated with androgen deprivation, decrease bone pain from metastases, and reduce skeletal related events. Denosumab, a RANK ligand inhibitor, is approved for the prevention of skeletal-related events in patients with bone metastases from prostate cancer and also appears to delay the development of these metastases.

Docetaxel is the first cytotoxic chemotherapy agent to improve survival in patients with hormone-refractory
prostate cancer. Current research is underway combining docetaxel with androgen deprivation therapy, radiation therapy, and surgery to determine whether combinations are effective in patients with high-risk prostate cancer. Immune therapies are also under investigation and have shown promise for patients with advanced prostate cancer. Sipuleucel-T, an autologous cellular immunotherapy, is FDA approved in asymptomatic or minimally symptomatic men with metastatic hormone-refractory prostate cancer. Other agents—cabazitaxel and abiraterone—are also approved for advanced prostate cancer after clinical trials have demonstrated improvements in survival in men having received prior docetaxel, and it is expected that MDV3100, cabozantinib, and alpharadin will be approved shortly.

## Prognosis

The likelihood of success of surveillance or treatment can be predicted using risk assessment tools that usually combine stage, grade, PSA level, and number and extent of positive prostate biopsies. Several tools are available on the Internet (eg, http://mskcc.org/mskcc/html/5794.cfm). One of the most widely used is the Kattan nomogram; it incorporates tumor stage, grade, and PSA level to predict the likelihood that a patient will be disease-free after radical prostatectomy or radiation therapy.

The University of California San Francisco CAPRA nomogram uses serum PSA, Gleason grade, clinical stage, percent positive biopsies, and patient age in a point system to risk stratify and predict the likelihood of PSA recurrence 3 and 5 years after radical prostatectomy (Tables 39–9 and 39–10). The CAPRA has been validated on large multicenter and international radical prostatectomy cohorts.

</table>
The patterns of prostate cancer progression have been well defined. Small and well-differentiated cancers (Gleason grades 1 and 2) are usually confined within the prostate, whereas large-volume (> 4 mL) or poorly differentiated (Gleason grades 4 and 5) cancers are more often locally extensive or metastatic to regional lymph nodes or bone. Penetration of the prostate capsule by cancer is common and occurs along perineural spaces. Seminal vesicle invasion is associated with a high likelihood of regional or distant disease, and disease recurrence. Lymphatic metastases can be identified in the obturator and internal iliac lymph node chains. The axial skeleton, as mentioned previously, is the most common site of distant metastases.

### When to Refer
- All patients should be referred to an urologist. PSA remains integral in prostate cancer diagnosis. Low-risk disease may be managed by active surveillance, surgery, or radiation therapy.
- High-risk disease often requires multimodal treatment strategies.

### BLADDER CANCER

#### ESSENTIALS OF DIAGNOSIS
- Gross or microscopic hematuria.
- Irritative voiding symptoms.
- Positive urinary cytology in most patients.
- Filling defect within bladder noted on imaging.

#### General Considerations

Bladder cancer is the second most common urologic cancer; it occurs more commonly in men than women (3:1:1), and the mean age of patients at diagnosis is 73 years. Cigarette smoking and exposure to industrial dyes or solvents are risk factors for the disease and account for approximately 60% and 15% of new cases, respectively. Ninety-eight percent of primary bladder cancers are epithelial malignancies, with the majority being urothelial cell carcinomas (90%). Adenocarcinomas and squamous cell cancers account for approximately 2% and 7%, respectively, of all bladder cancers detected in the United States. The latter is often associated with schistosomiasis, vesical calculi, or prolonged catheter use.

#### Clinical Findings

A. Symptoms and Signs

Hematuria—gross or microscopic, chronic or intermittent—is the presenting symptom in 85–90% of patients with bladder cancer (also see the section on Hematuria, in

PSA, prostate-specific antigen.
Chapter 23). Irritative voiding symptoms (urinary frequency and urgency) occur in a small percentage of patients as a result of the location or size of the cancer. Most patients with bladder cancer do not have signs of the disease because of its superficial nature. Abdominal masses detected on bimanual examination may be present in patients with large-volume or deeply infiltrating cancers. Hepatomegaly or palpable lymphadenopathy may be present in patients with metastatic disease, and lymphedema of the lower extremities may be present as a result of locally advanced cancers or metastases to pelvic lymph nodes.

### B. Laboratory Findings

Urinalysis reveals microscopic or gross hematuria in the majority of cases. On occasion, hematuria may be accompanied by pyuria. Azotemia may be present in a small number of cases associated with ureteral obstruction. Anemia may occasionally be due to chronic blood loss or to bone marrow metastases. Exfoliated cells from normal and abnormal urothelium can be readily detected in voided urine specimens. Cytology can be useful in detecting the disease at the time of initial presentation or to detect recurrence. Cytology is sensitive in detecting cancers of higher grade and stage (80–90%) but less so in detecting superficial or well-differentiated lesions (50%). There are numerous urinary tumor markers under investigation for screening, assessing recurrence, progression, prognosis or response to therapy; the NMP22 point-of-care assay for a specific urinary protein has shown utility in detecting recurrent tumors.

### C. Imaging

Bladder cancers may be identified using ultrasound, CT, or MRI where masses within the bladder are noted. However, the presence of cancer is confirmed by cystoscopy and biopsy, with imaging primarily used to evaluate the upper urinary tract and stage more advanced lesions.

### D. Cystourethroscopy and Biopsy

The diagnosis and staging of bladder cancers are made by cystoscopy and transurethral resection. If cystoscopy—performed usually under local anesthesia—confirms the presence of bladder cancer, the patient is scheduled for transurethral resection under general or regional anesthesia. Random bladder and, on occasion, prostate urethral biopsies are performed to detect occult disease elsewhere in the bladder and potentially identify patients at greater risk for tumor recurrence and progression.

### Pathology & Staging

Grading is based on cellular features: size, pleomorphism, mitotic rate, and hyperchromatism. Bladder cancer staging is based on the extent of bladder wall penetration and the presence of regional or distant metastases.

The natural history of bladder cancer is based on two separate but related processes: tumor recurrence within the bladder and progression to higher-stage disease. Both are correlated with tumor grade and stage.

### Treatment

Patients with superficial cancers (Ta, T1) are treated with complete transurethral resection and selective use of intravesical chemotherapy. In the subset of patients with large, high-grade, recurrent Ta lesions or T1 cancers and those with carcinoma in situ are good candidates for adjuvant intravesical therapy.

Patients with invasive (T2, T3) but still localized cancers are at risk for both nodal metastases and progression and require radical cystectomy, irradiation, or the combination of chemotherapy and selective surgery or irradiation due to the much higher risk of progression compared with patients with lower-stage lesions.

For patients with muscle invasive (T2 or greater) transitional cell carcinoma, neoadjuvant systemic chemotherapy prior to radical cystectomy is superior to radical cystectomy alone. This is particularly important for higher stage or bulky tumors in order to improve their surgical resectability.

### A. Intravesical Chemotherapy

Immunotherapeutic or chemotherapeutic agents delivered directly into the bladder via a urethral catheter can reduce the likelihood of recurrence in those who have undergone complete transurethral resection. Most agents are administered weekly for 6–12 weeks. Efficacy may be increased by prolonging contact time to 2 hours. The use of maintenance therapy after the initial induction regimen is beneficial. Common agents include thiotepa, mitomycin, doxorubicin, and BCG, the last being the most effective agent when compared with the others with respect to reducing disease progression. Side effects of intravesical chemotherapy include irritative voiding symptoms and hemorrhagic cystitis. Patients in whom symptoms or infection develop from BCG may require antituberculous therapy.

### B. Surgical Treatment

Although transurethral resection is the initial form of treatment for all bladder tumors since it is diagnostic, allows for proper staging, and controls superficial cancers, muscle-infiltrating cancers require more aggressive treatment. Partial cystectomy is indicated in selected patients with solitary lesions or those with cancers in a bladder diverticulum. Radical cystectomy entails removal of the bladder, prostate, seminal vesicles, and surrounding fat and peritoneal attachments in men and the uterus, cervix, urethra, anterior vaginal vault, and usually the ovaries in women. Bilateral pelvic lymph node dissection is performed in all patients.

Urinary diversion can be performed using a conduit of small or large bowel. However, continent forms of diversion have been developed that avoid the necessity of an external appliance and can be considered in a significant number of patients.

### C. Radiotherapy

External beam radiotherapy delivered in fractions over a 6- to 8-week period is generally well tolerated, but approximately 10–15% of patients will develop bladder,
bowel, or rectal complications. Local recurrence is common after radiotherapy alone (30–70%) and is therefore combined with systemic chemotherapy in an effort to reduce the need for radical cystectomy or to treat patients who are poor candidates for radical cystectomy.

**D. Chemotherapy**

Metastatic disease is present in 15% of patients with newly diagnosed bladder cancer, and metastases develop within 2 years in up to 40% of patients who were believed to have localized disease at the time of cystectomy or definitive radiotherapy. Cisplatin-based combination chemotherapy results in partial or complete responses in 15–45% of patients (see Table 39–4).

Combination chemotherapy has been integrated into trials of surgery and radiotherapy. It has been used to decrease recurrence rates with both modalities and to attempt bladder preservation in those treated with radiation. Chemotherapy should be considered before surgery in those with bulky lesions or those suspected of having regional disease, and recent evidence suggests that neo-adjuvant chemotherapy may benefit all patients with muscle-invasive disease prior to planned cystectomy. Chemoradiation is best suited for those with T2 or limited T3 disease without ureteral obstruction. Alternatively, chemotherapy has been used after cystectomy in patients at high risk for recurrence, such as those who have lymph node involvement or local invasion.

**Prognosis**

The frequency of recurrence and progression are correlated with grade. Whereas progression may be noted in few grade I cancers (19–37%), it is common with poorly differentiated lesions (33–67%). Carcinoma in situ is most often found in association with papillary bladder cancers. Its presence identifies patients at increased risk for recurrence and progression.

At initial presentation, approximately 50–80% of bladder cancers are superficial: stage Ta, Tis, or T1. When properly treated, lymph node metastases and progression are uncommon in this population and survival is excellent at 81%. Five-year survival of patients with T2 and T3 disease ranges from 50% to 75% after radical cystectomy. Long-term survival for patients with metastatic disease at presentation is rare.

**When to Refer**

- All patients should be referred to an urologist. Hematuria often deserves evaluation with upper urinary tract imaging and cystoscopy, particularly in a high-risk group (ie, older men).
- Histologic diagnosis and staging require endoscopic resection of tumor.

---

**CANCERS OF THE URETER & RENAL PELVIS**

Cancers of the renal pelvis and ureter are rare and occur more commonly in patients with bladder cancer, smokers, those with Balkan nephropathy, those exposed to Thorotrast (a contrast agent with radioactive thorium in use until the 1960s), or those with a long history of analgesic abuse. The majority are urothelial cell carcinomas. Gross or microscopic hematuria is present in most patients, and flank pain secondary to bleeding and obstruction occurs less commonly. Like primary bladder tumors, urinary cytology is often positive. The most common signs identified at the time of intravenous urography or CT include an intraluminal filling defect, unilateral nonvisualization of the collecting system, and hydronephrosis. Ureteral and renal pelvic tumors must be differentiated from calculi, blood clots, papillary necrosis, or inflammatory and infectious lesions. On occasion, upper urinary tract lesions are accessible for biopsy, fulguration, or resection using a ureteroscope. Treatment is based on the site, size, grade, depth of penetration, and number of tumors present. Most are excised with laparoscopic or open nephroureterectomy (renal pelvic and upper ureteral lesions) or segmental excision of the ureter (distal ureteral lesions). Endoscopic resection may be indicated in patients with limited renal function or focal, low-grade, cancers.

**RENAL CELL CARCINOMA**

- Gross or microscopic hematuria.
- Flank pain or mass in some patients.
- Systemic symptoms such as fever, weight loss may be prominent.
- Solid renal mass on imaging.

---

**General Considerations**

Renal cell carcinoma accounts for 2.6% of all adult cancers. In the United States, approximately 60,000 cases of renal cell carcinoma are diagnosed and 12,500 deaths result from it each year.
annually. Renal cell carcinoma has a peak incidence in the sixth decade of life and a male-to-female ratio of 2:1. It may be associated with a number of paraneoplastic syndromes (see below and Table 39–2).

The cause is unknown. Cigarette smoking is the only significant environmental risk factor that has been identified. Familial settings for renal cell carcinoma have been identified (von Hippel–Lindau syndrome, hereditary papillary renal cell carcinoma, hereditary leiomyoma-renal cell carcinoma, Birt-Hogg-Dube syndrome) as well as an association with dialysis-related acquired cystic disease and specific genetic aberrations (eg, Xp11.2 translocation), but sporadic tumors are far more common.

Renal cell carcinoma originates from the proximal tubule cells. Various histologic cell types are recognized (clear cell, papillary, chromophobe, collecting duct and tubule cells). Various histologic cell types are recognized sporadic tumors are far more common.

Renal cell carcinoma originates from the proximal tubule cells. Various histologic cell types are recognized (clear cell, papillary, chromophobe, collecting duct and sarcomatoid).

### Clinical Findings

#### A. Symptoms and Signs

Historically, 60% of patients presented with gross or microscopic hematuria. Flank pain or an abdominal mass was detected in approximately 30% of cases. The triad of flank pain, hematuria, and mass was found in only 10–15% of patients and is often a sign of advanced disease. Fever may be present as a paraneoplastic symptom (see Table 39–2). Symptoms of metastatic disease (cough, bone pain) occur in 20–30% of patients at presentation. Because of the widespread use of ultrasound and CT scanning, renal tumors are frequently detected incidentally in individuals with no urologic symptoms. There has been profound stage migration toward lower stages of disease over the past 10 years, likely due to the increased use of abdominal imaging. However, population mortality rates remain stable.

#### B. Laboratory Findings

Hematuria is present in 60% of patients. Erythrocytosis from increased erythropoietin production occurs in 5%, though anemia is more common; hypercalcemia may be present in up to 10% of patients. Stauffer syndrome is a reversible syndrome of hepatic dysfunction (with elevated liver function tests) in the absence of metastatic disease.

#### C. Imaging

Solid renal masses are often first identified by abdominal ultrasonography or CT. CT and MRI scanning are the most valuable imaging tests for renal cell carcinoma. It confirms the character of the mass and further stages the lesion with respect to regional lymph nodes, renal vein, or hepatic involvement. CT and MRI also provide valuable information regarding the contralateral kidney (function, bilaterality of neoplasm). Chest radiographs exclude pulmonary metastases, and bone scans should be performed for large tumors and in patients with bone pain or elevated alkaline phosphatase levels. MRI and duplex Doppler ultrasonography are excellent methods of assessing for the presence and extent of tumor thrombus within the renal vein or vena cava.

### Differential Diagnosis

Solid lesions of the kidney are renal cell carcinoma until proved otherwise. Other solid masses include angiomylipomas (fat density usually visible by CT), urothelial cell cancers of the renal pelvis (more centrally located, involvement of the collecting system, positive urinary cytologic tests), adrenal tumors (superior to the kidney) and oncocytomas (indistinguishable from renal cell carcinoma preoperatively), and renal abscesses.

### Treatment

Surgical extirpation is the primary treatment for localized renal cell carcinoma. Patients with a single kidney, bilateral lesions, or significant medical renal disease should be considered for partial nephrectomy. Patients with a normal contralateral kidney and good renal function but a small cancer are also candidates for partial nephrectomy, while radical nephrectomy is indicated in cases of larger tumors (> 7 cm) and those where partial nephrectomy is not technically feasible. The use of radiofrequency or cryosurgical ablation is being studied and likely yield equivalent short-term oncologic outcomes with reduced morbidity.

No effective chemotherapy is available for metastatic renal cell carcinoma. Vinblastine is the single most efficacious agent, with short-term partial response rates of 15%. Bevacizumab can prolong time to progression in those with metastatic disease (see Table 39–4). Biologic response modifiers have received much attention, including interferon-α and interleukin-2. Partial response rates of 15–20% and 15–35%, respectively, have been reported. Responders tend to have lower tumor burdens, metastatic disease confined to the lung, and a high performance status. Patients with metastatic kidney cancer and good performance status who have resectable primary tumors should undergo cytoreductive nephrectomy. Two randomized trials have shown a survival benefit of surgery followed by the use of systemic therapy—specifically, biologic response modifiers—compared with the use of systemic therapy alone.

Several targeted drugs, specifically VEGF, Raf-kinase, and mTOR inhibitors, are effective (40% response rates) in patients with advanced kidney cancer. The drugs are oral agents, well tolerated, and particularly active for clear cell carcinoma. The appropriate timing and combination of these agents, with and without surgery and cytokine therapy, remains to be determined.

### Prognosis

After radical or partial nephrectomy, tumors confined to the renal capsule (T1–T2) demonstrate 5-year disease-free survivals of 90–100%. Tumors extending beyond the renal capsule (T3 or T4) and node-positive tumors have 50–60% and 0–15% 5-year disease-free survival, respectively. One subgroup of patients with nonlocalized disease has reasonable long-term survival, namely, those with solitary resectable metastases. In this setting, radical nephrectomy with resection of the metastasis results in 5-year disease-free survival rates of 15–30%.
• Patients with solid renal masses or complex cysts require further evaluation and should be referred to an urologist.

• Surgical excision of renal cell carcinoma remains the gold standard.

• Patients with metastatic disease should be referred to an oncologist.

The kidney is not an infrequent site for metastatic disease. Of the solid tumors, lung cancer is the most common (20%), followed by breast (10%), stomach (10%), and the contralateral kidney (10%). Lymphoma, both Hodgkin and non-Hodgkin, may also involve the kidney, although it tends to appear as a diffusely infiltrative process resulting in renal enlargement rather than a discrete mass.

**PRIMARY TUMORS OF THE TESTIS**

**ESSENTIALS OF DIAGNOSIS**

- Most common neoplasm in men aged 20–35 years.
- Patient typically discovers a painless nodule.
- Orchiectomy necessary for diagnosis.

**General Considerations**

Malignant tumors of the testis are rare, with approximately five to six cases per 100,000 males reported in the United States each year. Ninety to 95 percent of all primary testicular tumors are germ cell tumors and can be divided into two major categories: nonseminomas, including embryonal cell carcinoma (20%), teratoma (5%), choriocarcinoma (<1%), and mixed cell types (40%); and seminomas (35%). The remainder of primary testicular tumors are nongerminal neoplasms (Leydig cell, Sertoli cell, gonadoblastoma). The lifetime probability of developing testicular cancer is 0.3% for an American male. For the purposes of this review, only germ cell tumors will be considered.

Approximately 5% of testicular tumors develop in a patient with a history of cryptorchism, with seminoma being the most common. However, 5–10% of these tumors occur in the contralateral, normally descended testis. The relative risk of development of malignancy is highest for the infra-abdominal testis (1:20) and lower for the inguinal testis (1:80). Placement of the cryptorchid testis into the scrotum (orchidopexy) does not alter the malignant potential of the cryptorchid testis but does facilitate routine examination and tumor detection.

Testicular cancer is slightly more common on the right than the left, paralleling the increased incidence of cryptorchidism on the right side. One to 2 percent of primary testicular tumors are bilateral and up to 50% of these men have a history of unilateral or bilateral cryptorchidism. Primary bilateral testicular tumors may occur synchronously or asynchronously but tend to be of the same histology. Seminoma is the most common histologic finding in bilateral primary testicular tumors, while malignant lymphoma is the most common bilateral testicular tumor overall.

In animal models, exogenous estrogen administration during pregnancy has been associated with an increased development of testicular tumors with relative risk ranging from 2.8 to 5.3. Other acquired factors such as trauma and infection-related testicular atrophy have been associated with testicular tumors; however, a causal relationship has not been established.

**Clinical Findings**

**A. Symptoms and Signs**

The most common symptom of testicular cancer is painless enlargement of the testis. Sensations of heaviness are
not unusual. Patients are usually the first to recognize an abnormality, yet the typical delay in seeking medical attention ranges from 3 to 6 months. Acute testicular pain resulting from intratesticular hemorrhage occurs in approximately 10% of cases. Ten percent of patients are asymptomatic at presentation, and 10% manifest symptoms relating to metastatic disease such as back pain (retroperitoneal metastases), cough (pulmonary metastases), or lower extremity edema (vena cava obstruction).

A discrete mass or diffuse testicular enlargement is noted in most cases. Secondary hydroceles may be present in 5–10% of cases. In advanced disease, supraclavicular adenopathy may be present, and abdominal examination may reveal a mass. Gynecomastia is seen in 5% of germ cell tumors.

**B. Laboratory Findings**

Several serum markers are important in the diagnosis and monitoring of testicular carcinoma, including human chorionic gonadotropin (hCG), α-fetoprotein, and lactate dehydrogenase. α-Fetoprotein is never elevated with pure seminomas, and while hCG is occasionally elevated in seminomas, levels tend to be lower than those seen with nonseminomas. Lactate dehydrogenase may be elevated with either type of tumor. Liver function tests may be elevated in the presence of hepatic metastases, and anemia may be present in advanced disease.

**C. Imaging**

Scrotal ultrasound can readily determine whether a mass is intratesticular or extratesticular. Once the diagnosis of testicular cancer has been established by inguinal orchectomy, clinical staging of the disease is accomplished by chest, abdominal, and pelvic CT scanning.

**Staging**

In a commonly used staging system for nonseminoma germ cell tumors, a stage A lesion is confined to the testis; stage B demonstrates regional lymph node involvement in the retroperitoneum; and stage C indicates distant metastasis. For seminoma, the M.D. Anderson system is commonly used. In this system, a stage I lesion is confined to the testis, a stage II lesion has spread to the retroperitoneal lymph nodes, and a stage III lesion has supradiaphragmatic nodal or visceral involvement.

**Differential Diagnosis**

An incorrect diagnosis is made at the initial examination in up to 25% of patients with testicular tumors. Scrotal ultrasonography should be performed if any uncertainty exists with respect to the diagnosis. Although most intratesticular masses are malignant, a benign lesion—epididymal cyst—may rarely be seen. Epididymal cysts are usually very small benign nodules located just underneath the tunica albuginea; occasionally, however, they can be large.

**Treatment**

Inguinal exploration with early vascular control of the spermatic cord structures is the initial intervention. If cancer cannot be excluded by examination of the testis, radical orchectomy is warranted. Scrotal approaches and open testicular biopsies should be avoided. Further therapy depends on the histology of the tumor as well as the clinical stage.

Up to 75% of clinical stage I nonseminomas are cured by orchietomy alone. Selected patients who meet specific criteria may be offered surveillance after orchietomy. These criteria are as follows: (1) tumor is confined within the tunica albuginea; (2) tumor does not demonstrate vascular invasion; (3) tumor markers normalize after orchietomy; (4) radiographic imaging of the chest and abdomen shows no evidence of disease; and (5) the patient is reliable. Patients most likely to experience relapse on a surveillance regimen include those with predominantly embryonal cancer and those with vascular or lymphatic invasion identified in the orchietomy specimen.

Stage I and IIA/b seminomas (retroperitoneal disease < 2 cm/2–5 cm in diameter) are treated by radical orchietomy and retroperitoneal irradiation. Patients with clinical stage I disease may be candidates for surveillance or single-agent carboplatin. Seminomas of stage IIC (> 5 cm retroperitoneal involvement) and stage III receive primary chemotherapy (etoposide and cisplatin or cisplatin, etoposide, and bleomycin) (Table 39–4). Surgical resection of residual retroperitoneal masses is warranted if the mass is > 3 cm in diameter, under which circumstances 40% will harbor residual carcinoma.

Surveillance needs to be considered an active process both by the clinician and by the patient. Patients are followed monthly for the first 2 years and bimonthly in the third year. Tumor markers are obtained at each visit, and chest radiographs and CT scans are obtained every 3 months. Follow-up continues beyond the initial 3 years; however, 80% of relapses will occur within the first 2 years. With rare exceptions, patients who relapse can be cured by chemotherapy or surgery. Alternatives to surveillance for clinical stage I nonseminoma include adjuvant chemotherapy (bleomycin, etoposide, cisplatin) (see Table 39–4) or retroperitoneal lymph nodes dissection.

Patients with bulky retroperitoneal disease (> 5 cm nodes) or metastatic nonseminomas are treated with primary cisplatin-based combination chemotherapy following orchietomy (etoposide and cisplatin or cisplatin, etoposide, and bleomycin). If tumor markers normalize and a residual mass > 1 cm persists on imaging studies, the mass is resected because 15–20% of the time it will harbor viable cancer and 40% of the time it will harbor teratoma. Even if patients have a complete response to chemotherapy, some clinicians advocate retroperitoneal lymphadenectomy since 10% of patients may harbor residual carcinoma and 10% may have teratoma in the retroperitoneum. If tumor markers fail to normalize following primary chemotherapy, salvage chemotherapy is required (cisplatin, etoposide, ifosfamide).

**Prognosis**

The 5-year disease-free survival rate for patients with stage A nonseminomas (includes all treatments) ranges from 96% to 100%. For low-volume stage B disease, 90% 5-year
SECONDARY TUMORS OF THE TESTIS

Secondary tumors of the testis are rare. In men over the age of 50 years, lymphoma is the most common testis tumor, and overall it is the most common secondary neoplasm of the testis, accounting for 5% of all testicular tumors. It may be seen in three clinical settings: (1) late manifestation of widespread lymphoma, (2) the initial presentation of clinically occult disease, and (3) primary extranodal disease. Radical orchiectomy is indicated to make the diagnosis. Prognosis is related to the stage of disease.

Metastasis to the testis is rare. The most common primary site of origin is the prostate, followed by the lung, gastrointestinal tract, melanoma, and kidney.

CANCER COMPLICATIONS & EMERGENCIES

SPINAL CORD COMPRESSION

General Considerations

Cancers that cause spinal cord compression most commonly metastasize to the vertebral bodies, resulting in physical damage to the spinal cord from edema, hemorrhage, and pressure-induced ischemia to the vasculature of the spinal cord. Persistent compression can result in irreversible changes to the myelin sheaths resulting in permanent neurologic impairment.

Prompt diagnosis and therapeutic intervention are essential, since the probability of reversing neurologic symptoms largely depends on the duration of symptoms. Patients who are treated promptly after symptoms appear may have partial or complete return of function and, depending on tumor sensitivity to specific treatment, may respond favorably to subsequent anticancer therapy.

Clinical Findings

A. Symptoms and Signs

Back pain at the level of the tumor mass occurs in over 80% of cases and may be aggravated by lying down, weight bearing, sneezing, or coughing; it usually precedes the development of neurologic symptoms or signs. Since involvement is usually epidural, a mixture of nerve root and spinal cord symptoms often develops. Progressive weakness and sensory changes commonly occur. Bowel and bladder symptoms progressing to incontinence are late findings.

The initial findings of impending cord compression may be quite subtle, and there should be a high index of suspicion when back pain or weakness of the lower extremities develops in cancer patients.

B. Imaging

MRI is usually the initial imaging procedure of choice in a cancer patient with new-onset back pain. When there are neurologic findings suggesting spinal cord compression, an emergent MRI should be obtained; the MRI should include a survey of the entire spine in order to define all areas of tumor involvement for treatment planning purposes.
Bone radiographs, if done, may show evidence of vertebral body or pedicle destruction by the cancer. However, bone radiographs are neither sensitive nor specific and therefore are not helpful in diagnosis or treatment planning. If the back pain symptoms are nonspecific, bone scan imaging may be useful as a screening procedure.

**Clinical Findings**

**A. Symptoms and Signs**

Patients with pleural and pericardial effusions complain of shortness of breath and orthopnea. Patients with ascites complain of abdominal distention and discomfort. Cardiac tamponade causing pressure equalization in the chambers impairing both filling and cardiac output can be a life-threatening event. Signs of tamponade include tachycardia, pulsus paradoxus, and hypotension. Signs of pleural effusions include decreased breath sounds, egophony, and percussion dullness.

**B. Laboratory Findings**

Malignancy is confirmed as the cause of an effusion when analysis of the fluid specimen shows malignant cells in either the cytology or cell block specimen.

**C. Imaging**

The presence of effusions can be confirmed with radiographic studies or ultrasonography.

**Differential Diagnosis**

The differential diagnosis of a malignant exudative pleural or pericardial effusion includes nonmalignant processes, such as infection, pulmonary embolism, congestive heart failure, and trauma. Malignant effusions are rarely transudative.

The differential diagnosis of malignant ascites includes similar benign processes, such as congestive heart failure and infections; cirrhosis and pancreatic disease also cause ascites.

Bloody effusions are usually due to cancer, but a bloody pleural effusion can also be due to pulmonary embolism, trauma and, occasionally, infection. Chylous pleural or ascitic fluid is generally associated with obstruction of lymphatic drainage as might occur in lymphomas.

**Treatment**

In some cases, treatment of the underlying cancer with chemotherapy can cause regression of the effusions; however, not uncommonly, the presence of an effusion is an end-stage manifestation of the disease. In this situation, decisions regarding management are in large part dictated by the patient’s symptoms and goals of care.

**A. Pleural Effusion**

A pleural effusion that is symptomatic may be managed initially with a large volume thoracentesis. With some patients, the effusion slowly reaccumulates, which allows...
chest tube drainage followed by pleurodesis is the preferred option for patients with a reasonable life expectancy. The procedure involves placement of a chest tube that is connected to closed water seal drainage. After lung expansion is confirmed on a chest radiograph, a sclerosing agent (such as talc slurry or doxycycline) is injected into the catheter. Patients should be premedicated with analgesics and placed in a variety of positions in order to distribute the drug through the pleural spaces. Previously, injection of the sclerosing agent was done only after drainage had decreased to < 100 mL/d; but it is now clear that effective sclerosis can be achieved after 24 hours of drainage regardless of the amount of the residual fluid. Pleurodesis will not be successful if the lung cannot be reexpanded; these patients may be treated with the placement of a shunt or an indwelling catheter. Placement of an indwelling catheter that can be drained by a family member or a visiting nurse may also be preferable for patients with short life expectancies or for those who do not respond to pleurodesis.

B. Pericardial Effusion

Fluid may be removed by a needle aspiration or by placement of a catheter for more thorough drainage. As with pleural effusions, most pericardial effusions will reaccumulate. Management options for recurrent, symptomatic effusions include catheter drainage followed by sclerosis with such agents as doxycycline or bleomycin or by pericardectomy.

C. Malignant Ascites

Patients with malignant ascites not responsive to chemotherapy are generally treated with repeated large volume paracenteses. As the frequency of drainage to maintain comfort can compromise the patient’s quality of life, other alternatives include placement of a catheter or port so that the patient, family member, or visiting nurse can drain fluid as needed at home. Another option is placement of a peritoneovenous shunt; this can be considered for a select group of patients with life expectancy > 3 months and fluid that is nonviscous, nonbloody, and nonloculated.

HYPERCALCEMIA

ESSENTiALs Of DIAgnOSis

- Usually symptomatic and severe (≥ 15 mg/dL (> 3.75 mmol/L)).
- Most common paraneoplastic endocrine syndrome; accounts for most inpatients with hypercalcemia.
- The neoplasm is clinically apparent in nearly all cases when hypercalcemia is detected.

General Considerations

Hypercalcemia affects 20–30% of cancer patients at some point during their illness. The most common cancers causing hypercalcemia are myeloma, breast carcinoma, and non–small cell lung cancer. The presence of bone metastases is not an essential feature of the syndrome, since hypercalcemia can be caused by systemic effects of tumor–released proteins (see The Paraneoplastic Syndromes above).

Clinical Findings

A. Symptoms and Signs

Symptoms and signs of hypercalcemia can be subtle; more severe symptoms occur with higher levels of hypercalcemia and with a rapid rate at which the calcium level rises. Early symptoms typically include anorexia, nausea, fatigue, constipation, and polyuria; later findings may include muscular weakness and hyporeflexia, confusion, psychosis, tremor, and lethargy.

B. Laboratory Findings

Symptoms and signs are caused by free calcium; as calcium is bound by protein in the serum, the measured serum calcium will underestimate the free or ionized calcium in patients with low albumin levels. In the setting of hypoalbuminemia, the corrected serum calcium should be calculated by one of several available formulas (eg, corrected calcium = measured calcium – measured albumin + 4). Alternatively, the free calcium can be measured. When the corrected serum calcium rises above 12 mg/dL (3 mmol/L), sudden death due to cardiac arrhythmia or asystole may occur. The presence of hypercalcemia does not invariably indicate a dismal prognosis, especially in patients with breast cancer, myeloma, or lymphoma.

In the absence of signs or symptoms of hypercalcemia, a laboratory finding of elevated serum calcium should be retested immediately to exclude the possibility of error.

C. ECG

Electrocardiography often shows a shortening of the QT interval.

Treatment

Emergency management should begin with the initiation of intravenous fluids with 0.9% saline at 100–200 mL/h to
ensure rehydration with brisk urinary output of the often volume-depleted patient. If kidney function is normal or only marginally impaired, a bisphosphonate should be given. Choices include pamidronate, 60–90 mg intravenously over 2–4 hours, or zoledronic acid, 4 mg intravenously over several minutes. Zoledronic acid is more potent than pamidronate and has the advantage of a shorter administration time as well as a longer duration of effect but is more associated with the uncommon but serious side effect of osteonecrosis of the jaw. Once hypercalcemia is controlled, treatment directed at the cancer should be initiated if possible. Commonly, though, hypercalcemia occurs in patients with cancers that are unresponsive to treatment. In the event that the hypercalcemia becomes refractory to repeated doses of bisphosphonates, other agents that can help control hypercalcemia (at least temporarily) include gallium nitrate, calcitonin, and mithramycin; corticosteroids can be useful in patients with myeloma and lymphoma. Salmon calcitonin, 4–8 international units/kg given subcutaneously or intramuscularly every 12 hours, can be useful in patients with kidney disease; its onset of action is within hours but its hypocalcemic effect will wane in 2–3 days.

Prevention is the most important factor in the management of TLS. Published guidelines for TLS management include aggressive hydration prior to initiation of chemotherapy as well as during and after completion of the chemotherapy. Administration of fluid helps keep urine flowing and facilitates excretion of uric acid and phosphorus. For the patients with moderate risk of developing TLS, for instance, those with intermediate grade lymphomas and acute leukemias, allopurinol (which blocks the enzyme xanthine oxidase and therefore the formation of uric acid from purine breakdown) should be given before starting chemotherapy at an oral dose of 100 mg/m² every 8 hours (maximum 800 mg/d) with dose reductions for impaired kidney function. For patients at high risk for developing TLS, for instance, patients with high-grade lymphomas or patients with acute leukemias and markedly elevated white blood cell counts (with acute myeloid leukemia, white blood cell count > 50,000/mcL [> 50,000/10⁹/L]; with acute lymphoblastic leukemia, white blood cell count > 100,000/mcL [> 100,000/10⁹/L]) or in whom hyperuricemia develops despite treatment with allopurinol, rasburicase 0.1–0.2 mg/kg/d is given intravenously for 1–7 days. Rasburicase is a recombinant urate oxidase that converts uric acid into the more soluble form resulting in rapid decline in uric acid levels. Rasburicase cannot be given to patients with known glucose-6-phosphate dehydrogenase (G6PD) deficiency nor can it be given to pregnant or lactating women. One of the mainstays of TLS management, systemic bicarbonate infusions to alkalinate the urine, is no longer routinely recommended. Laboratory values should be monitored following initiation of chemotherapy; elevated potassium or phosphorus levels need to be promptly managed.

**Clinical Findings**

Symptoms of hyperphosphatemia include nausea and vomiting as well as seizures. Also, with high levels of phosphorus, co-precipitation with calcium can cause renal tubule blockage further exacerbating the kidney injury. Hyperkalemia, due to release of intracellular potassium and impaired kidney excretion, can cause arrhythmias and sudden death.

**Treatment**

**General Considerations**

Tumor lysis syndrome (TLS) is seen most commonly following treatment of hematologic malignancies, such as acute lymphoblastic leukemia and Burkitt lymphoma. However, TLS can develop from any tumor highly sensitive to chemotherapy. TLS is caused by the massive release of cellular material including nucleic acids, proteins, phosphorus, and potassium. If both the metabolism and excretion of these breakdown products are impaired, hyperuricemia, hyperphosphatemia, and hyperkalemia will develop abruptly. Acute kidney injury may then develop from the crystallization and deposition of uric acid and calcium phosphate within the renal tubules further exacerbating the hyperphosphatemia and hyperkalemia.

**When to Refer**

Should urinary output drop, creatinine level rise, or hyperphosphatemia persist, a nephrologist should be immediately consulted to evaluate the need for dialysis.
Empiric antibiotic therapy needs to be initiated immediately in the febrile, neutropenic patient. The choice of antibiotics depends on a number of different factors including the patient’s clinical status and any localizing source of infection. If the patient is clinically well, monotherapy with an intravenous β-lactam with anti-

Pseudomonas activity (cefepime, ceftazidime, imipenem/cilastatin, piperacillin/tazobactam) should be started (see Infections in the Immunocompromised Patient, Chapter 30). If the patient is clinically ill with hypotension or hypoxia, an aminoglycoside or fluoroquinolone should be added for “double” gram-negative bacteria coverage. If there is a strong suspicion of a gram-positive organism, such as from S. aureus catheter infection, vancomycin can be given empirically. In some instances, patients may be treated with oral antibiotics and potentially in the outpatient setting. The Infectious Disease Society of America (IDSA) has published recommendations for antibiotic use in these low-risk patients. These patients must have an expected neutropenic timeframe of 7 days or less and not have comorbidities or signs of hemodynamic instability, gastrointestinal symptoms, altered mental status, pulmonary issues (an infiltrate, hypoxia, or underlying chronic obstructive pulmonary disease) and their liver and kidney function must not be impaired. If a patient is to be treated as an outpatient, he or she must also have good support at home and easy access to returning to the hospital if the clinical status worsens.

Antibiotics should be continued until the neutrophil count is rising and > 500/mcL (> 0.5 x 10⁹/L) for at least 1 day and the patient has been afebrile for 2 days. If an organism is identified through the cultures, the antibiotics should be adjusted to the antibiotic sensitivities of the isolate; treatment should be continued for the appropriate period of time and at least until the neutrophil count recovers.

For the neutropenic patient who is persistently febrile despite broad-spectrum antibiotics, an empiric antifungal drug should be added (amphotericin B, caspofungin, itraconazole, voriconazole, or liposomal amphotericin B).

### PRIMARY CANCER TREATMENT

#### SYSTEMIC CANCER THERAPY

Detailed guidelines from the NCCN for cancer treatment can be found at www.nccn.org.

Use of cytotoxic drugs, hormones, antihormones, and biologic agents has become a highly specialized and increasingly effective means of treating cancer, with therapy usually administered by a medical oncologist. Selection of specific drugs or protocols for various types of cancer has traditionally been based on results of prior clinical trials; however, many patients have drug-resistant infections.
tumors. Molecular mechanisms of drug resistance continue to be the subject of intense study. Described mechanisms of drug resistance include impaired membrane transport of drugs, enhanced drug metabolism, mutated target proteins, and blockage of apoptosis due to mutations in cell cycle -proteins. Cancer cells may initially be resistant to chemotherapy or acquire resistance when exposed to drugs.

### TOXICITY & DOSE MODIFICATION OF CHEMOTHERAPEUTIC AGENTS

Use of chemotherapy to treat cancer is generally guided by results from clinical trials in individual tumor types. The complexity of treating cancer has increased over the last decade as more drugs, including those with novel mechanisms of action, have been approved by the Food and Drug Administration and introduced into general practice. Drug side effects and toxicities must be anticipated and carefully monitored. The short- and long-term toxicities of individual drugs are listed in Tables 39–11 and 39–12. Decisions on dose modifications for toxicities should be guided by the intent of therapy. In the palliative setting where the aim of therapy is to improve symptoms and quality of life, lowering doses to minimize toxicity is commonly done. However, when the goal of treatment is cure, dosing frequency and intensity should be maintained whenever possible. Cancer chemotherapy should be given and monitored by a medical oncologist or hematologist.

A complete blood count consisting of a differential count with particular attention to the absolute neutrophil count and platelet count as well as tests of liver and kidney function should be obtained before the initiation of chemotherapy. In patients with normal blood counts as well as normal liver and kidney function, drugs are started at their full dose. When the intent of chemotherapy is cure, including treatment in the adjuvant setting, every attempt should be made to schedule chemotherapy on time and at full dose. A complete blood count with differential should be checked at mid cycle to determine the nadir of the absolute neutrophil and platelet counts as well as immediately before the next cycle of chemotherapy is due.

Dose reductions may be necessary for patients with impaired kidney or liver function depending on the clearance mechanism of the drug. For patients receiving chemotherapy for palliation, bone marrow toxicity can be managed with dose reductions or delaying the next treatment cycle. A schema for dose modification is shown in Table 39–13.

### 1. Bone Marrow Toxicity

#### A. Neutropenia

Granulocyte colony-stimulating factor (G-CSF), given as either daily subcutaneous injections (filgrastim, 300 mcg or 480 mcg) or as a one-time dose (pegfilgrastim, 6 mg) beginning 24–72 hours after cytotoxic chemotherapy is completed, has been shown to reduce the duration and severity of granulocytopenia following cytotoxic chemotherapy (Table 39–12). The American Society of Clinical Oncology and NCCN guidelines recommend primary prophylaxis with a G-CSF when there is 20% risk of febrile neutropenia or when the patient’s age, medical history, and disease characteristics make the patient at high risk for complications related to myelosuppression.

#### B. Anemia

Erythropoiesis-stimulating agents (ESAs) ameliorate the anemia and associated symptoms caused by cancer chemotherapy but these drugs have untoward effects, including an increased risk of thromboembolism, and even more concerning, potentially decreased survival due to cancer-related deaths. These findings have prompted the US Food and Drug Administration and other organizations (American Society of Hematology, American Society of Clinical Oncology, and NCCN) to issue advisories and guidelines limiting their use. The NCCN recommendation that these drugs should not be used when the intent of chemotherapy is curative is based on evidence that survival can be affected by the administration of ESAs. Studies done in patients with potentially curable head and neck, breast, and cervical cancers have shown inferior outcomes when ESAs were used. It is important to point out that the target hemoglobin used in these studies was higher than is currently recommended. Nonetheless, ESAs cannot be currently recommended when the intent of therapy is cure. The alternative to managing symptomatic anemia in these patients receiving curative chemotherapy is administration of red blood cell transfusions.

When using ESAs, treatment should not be initiated until the hemoglobin is < 10 g/dL (< 100 g/L) with the medication held when the hemoglobin is > 12 g/dL (> 120 g/L). Epoetin alfa can be given subcutaneously as a weekly dose of 30,000–40,000 units with a target hemoglobin of 11–12 g/dL (110–120 g/L) (see Table 39–12). Darbepoetin alfa is given subcutaneously every 2–3 weeks at a dose of 200–300 mcg with the same target hemoglobin. Patients need to be iron replete to have maximum therapeutic effect. Uncontrolled hypertension is a contraindication to the use of ESAs; blood pressure must be controlled prior to initiation of this therapy. The FDA mandates that prescribing clinicians receive specific education on use of ESAs, and patients receiving ESAs must be provided written material describing the risks and benefits of the drug.

#### C. Thrombocytopenia

Drug management of chemotherapy-induced thrombocytopenia is more limited. The only available drug, oprelvekin or recombinant interleukin-11, has modest activity in improving thrombocytopenia associated with chemotherapy; however, the side effects of fluid retention, congestive heart failure, and arrhythmias have limited its use. Thrombopoietin, the protein that stimulates megakaryopoiesis in vivo, was isolated in 1994. Despite much work attempting to produce a clinically effective thrombopoietin agent for therapeutic use, no such drug is commercially available for this indication. Two drugs that activate the thrombopoietin receptor and are approved for use in

narrowing of at least two central nervous system receptors, 5-hydroxytryptamine subtype 3 (5HT3) and neurokinin subtype 1 (NK1). Chemotherapy-induced nausea and vomiting can be acute, occurring within minutes to hours of chemotherapy administration, or delayed until the second day and lasting up to 7 days. Anticipatory nausea and vomiting may even occur before the administration of chemotherapy. Chemotherapy drugs or drug regimens are classified into high, moderate, low, and minimal likelihoods of causing emesis (90%, 30–90%, 10–30%, < 10%, respectively). Highly emetogenic chemotherapy drugs include cisplatin, carbustine, cyclophosphamide at doses over 1.5 g/m2, dacarbazine, mechlorethamine, and streptozocin. Chemotherapy drugs that are moderately emetogenic include doxorubicin, daunomycin, idarubicin, epirubicin, cyclophosphamide, irinotecan, oxaliplatin, ifosfamide, cytarabine, and carboplatin. Drugs with low emetic potential include bortezomib, docetaxel, etoposide, fluorouracil, cytarabine, and carboplatin. Drugs with minimal risk of emesis include bevacizumab, bleomycin, methotrexate, mitomycin, mitoxantrone, ifosfamide, cyclophosphamide, irinotecan, oxaliplatin, ifosfamide, cytarabine, and carboplatin. Drugs with low emetic potential include bortezomib, docetaxel, etoposide, fluorouracil, cyclophosphamide, irinotecan, oxaliplatin, ifosfamide, cytarabine, and carboplatin. Drugs with low emetic potential include bortezomib, docetaxel, etoposide, fluorouracil, cyclophosphamide, irinotecan, oxaliplatin, ifosfamide, cytarabine, and carboplatin.

By understanding the physiology of chemotherapy-induced nausea and vomiting, major advances have occurred with the development of highly effective antiemetic drugs. Antagonists to the 5HT3-receptor include ondansetron, granisetron, dolasetron, tropisetron, and palonosetron. Each of these drugs has similar efficacy. Ondansetron can be given either orally (5 mg) or intravenously (8 mg or 0.15 mg/kg) or orally (24 mg for highly emetogenic chemotherapy, 8 mg twice daily for moderately emetogenic chemotherapy). Doses of 8 mg can be repeated parenterally or orally every 8 hours. Dosing of granisetron is 1 mg or 0.01 mg/kg intravenously or 1–2 mg orally. Dolasetron is given 1.8 mg/kg or a fixed dose of 100 mg intravenously or 100 mg can be given orally. Tropisetron is given at a dose of 5 mg either orally or intravenously. Palonosetron, a long-acting 5HT3 receptor antagonist, has high affinity for the 5HT3-receptor given at a dose of 0.25 mg intravenously, is effective for not only acute but also delayed emesis. The efficacy of the 5HT3-receptor blockade is improved by adding 6–10 mg of either oral or intravenous dexamethasone.

Aprepitant is an antagonist to the NK1 receptor. When given as a 125-mg oral dose followed by 80 mg on the second and third days of chemotherapy, palonosetron can be given at a dose of 1 mg on day 1 and 0.75 mg on days 2 and 3. A suppository form of prochlorperazine, 25 mg, may be used for patients who are unable to swallow oral medications.

The importance of treating chemotherapy-induced nausea and vomiting expectantly and aggressively beginning with the first course of chemotherapy cannot be overemphasized. Patients being treated in the clinic setting should always be given antiemetics for home use with written instructions as well as contact numbers to call for advice.

3. Gastrointestinal Toxicity

Untoward effects of cancer chemotherapy include damage to the more rapidly growing cells of the body such as the mucosal lining from the mouth through the gastrointestinal tract. Oral symptoms range from mild to severe to frank ulcerations in the mouth. Not uncommonly, mouth ulcers will have superimposed candida or herpes simplex infections. In addition to receiving cytotoxic chemotherapy, a significant risk factor for development of oral mucositis is poor oral hygiene and existing caries or periodontal disease. Toxicity in the gastrointestinal tract usually manifests as diarrhea. Gastrointestinal symptoms can range from mild symptoms of loose stools to life-threatening diarrhea due to dehydration and electrolyte imbalances. Drugs most commonly associated with causing mucositis in the mouth and the gastrointestinal tract are cytarabine, 5-FU, and methotrexate.

Patients undergoing treatment for head and neck cancer with concurrent chemotherapy and radiation therapy have a very high risk of developing severe mucositis.

Preventive strategies for managing oral mucositis includes a pretreatment dental examination, particularly for all head and neck cancer patients and any cancer patient with poor dental hygiene who will be receiving chemotherapy. For patients receiving fluorouracil, simple measures such as ice chips in the mouth for 30 minutes during infusion can reduce the incidence and severity of mucositis. Once mucositis is encountered, superimposed fungal infections should be treated with topical anti-fungal medications (oral nystatin mouth suspensions, or clotrimazole troches) or systemic therapy (fluconazole 100–400 mg orally daily). Suspected herpetic infections can be treated with acyclovir (up to 800 mg orally five times daily) or valacyclovir (1 g orally twice daily). Mucositis may also be managed with mouthwashes; it is also important to provide adequate pain medication.

Newer strategies for prevention of oral mucositis include the recombinant keratinocyte growth factor inhibitor palifermin. Practice guidelines recommend prophylaxis with intravenous palifermin (60 mcg/kg/d) for patients receiving high-dose chemotherapy in order to reduce the incidence and duration of mucositis.

Diarrhea is most associated with fluorouracil, capecitabine, and irinotecan as well as the tyrosine kinase inhibitors, and prochlorperazine, 5–10 mg orally or intravenously every 8 hours. Lorazepam, in addition to antianxiety effects, has an antiemetic effect. Prochlorperazine is generally sufficient to treat patients receiving low emetogenic chemotherapy. A suppository form of prochlorperazine, 25 mg, may be used for patients who are unable to swallow oral medications.
(sorafenib, sunitinib, imatinib, dasatinib) and epithelial growth factor inhibitors ( cetuximab, panitumumab, and erlotinib). Mild to moderate diarrhea can be managed with oral antiarrhythmic medication (loperamide, 4 mg initially followed by 2 mg every 2–4 hours until bowel movements are formed). Occasionally, the diarrhea will be overwhelming causing dehydration, electrolyte imbalances, and acute kidney injury. These patients require inpatient management with aggressive intravenous hydration and replacement of electrolytes.

4. Skin Toxicity

Dermatologic complications from cancer chemotherapy can include hyperpigmentation (liposomal doxorubicin, busulfan, hydroxyurea) alopecia, photosensitivity, nail changes, acral erythema, and generalized rashes. Acral erythema, otherwise known as hand-foot syndrome and most commonly associated with administration of fluorouracil, capecitabine, and liposomal doxorubicin, manifests as painful palms or soles accompanied by erythema, progressing to blistering desquamation and ulceration in its worst forms. Management can include attempts at prevention with oral pyridoxine, 200 mg daily, and applying cold packs to the extremities while the chemotherapy is being administered. Agents targeting the epidermal growth factor pathway can cause an acne like rash; interestingly, the development of this rash may identify those who will respond to the drug. Inhibitors of the tyrosine kinase pathway are also associated with a high incidence of dermatologic complications, such as rash and acral erythema.

5. Miscellaneous Drug-Specific Toxicities

The toxicities of individual drugs have been summarized in Tables 39–11 and 39–12; however, several of these warrant additional mention, since they occur with frequently administered agents, and special measures are often indicated.

A. Hemorrhagic Cystitis Induced by Cyclophosphamide or Ifosfamide

Metabolic products of cyclophosphamide that retain cytotoxic activity are excreted into the urine. Some patients appear to metabolize more of the drug to these active excretory products; if their urine is concentrated, severe bladder damage may result. Patients receiving cyclophosphamide must maintain a high fluid intake prior to and following the administration of the drug and be counseled to empty their bladders frequently. Early symptoms suggesting bladder toxicity include dysuria and increased frequency or urination. Should microscopic hematuria develop, it is advisable to stop the drug temporarily or switch to a different alkylating agent, to increase fluid intake, and to administer a urinary analgesic such as phenazopyridine. With severe cystitis, large segments of bladder mucosa may be shed, resulting in prolonged gross hematuria. Such patients should be observed for signs of urinary obstruction and may require cystoscopy for removal of obstructing blood clots. The cyclophosphamide analog ifosfamide can cause severe hemorrhagic cystitis when used alone. However, when its use is followed by a series of doses of the neutralizing agent mesna, bladder toxicity can be prevented. Mesna can also be used for patients taking cyclophosphamide in whom cystitis develops.

B. Neuropathy Due to Vinca Alkaloids and Other Chemotherapy Drugs

Neuropathy is caused by a number of different chemotherapy drugs, the most common being vincristine. The peripheral neuropathy can be sensory, motor, autonomic, or a combination of these effects. In its mildest form, it consists of paresthesias of the fingers and toes. Occasionally, acute jaw or throat pain can develop after vincristine therapy. This may be a form of trigeminal neuralgia. With continued vincristine therapy, the paresthesias extend to the proximal interphalangeal joints, hyporeflexia appears in the lower extremities, and significant weakness can develop. Other drugs in the vinca alkaloid class as well as the taxane drugs (paclitaxel and docetaxel) and agents to treat myeloma (thalidomide and bortezomib) cause similar toxicity. The presence of neurologic symptoms is not in itself a reason to stop therapy; the severity of the symptoms must be balanced against the goals of therapy. Usually though, the presence of moderate to severe paresthesias or the detection of motor impairment would result in the decision to discontinue the drug.

Constipation is the most common symptom of autonomic neuropathy associated with the vinca alkaloids. Patients receiving these drugs should be started on stool softeners and mild cathartics when therapy is begun; otherwise, severe impaction may result from an atonic bowel. More serious autonomic involvement can lead to acute intestinal obstruction with signs indistinguishable from those of an acute abdomen. Bladder neuropathies are uncommon but may be severe. These two complications are absolute contraindications to continued vincristine therapy.

C. Methotrexate Toxicity

Methotrexate, a folate antagonist, is a commonly used drug and a key component of regimens to treat patients with leptomeningeal disease, acute lymphoblastic leukemia, and sarcomas. The dose used in intrathecal therapy is 12 mg. Methotrexate is almost entirely eliminated by the kidney. Methotrexate toxicity affects cells with rapid turnover, including the bone marrow and mucosa resulting in myelosuppression and mucositis. Methotrexate can also damage the liver and kidney manifesting as elevated liver enzymes and creatinine. High-dose methotrexate, usually defined as a dose of 500 mg/m² or more given over 4–36 hours, would be lethal without “rescue” of the normal tissues. Leucovorin, a form of folate, will reverse the toxic effects of methotrexate and is given until serum methotrexate levels are in the safe range (< 0.05 mmol/L). It is crucial that high-dose methotrexate and leucovorin are given precisely according to protocol as deviations of the timing of methotrexate delivery or delay in rescue can result in patient death. Lower doses of methotrexate can be problematic in patients with kidney disease who cannot
clear the drug normally or with patients who have effusions. In the latter instance, methotrexate distributes itself in effusions and will leak out continuously, exposing normal tissue to small but cumulatively toxic amounts of the drug. If methotrexate is given to a patient who either has or develops kidney disease or to a patient with an effusion, prolonged rescue with leucovorin will be necessary. Vigorous hydration and bicarbonate loading also appear to be important in preventing crystallization of high-dose methotrexate in the renal tubular epithelium and minimizing the possibility of nephrotoxicity. Daily monitoring of the serum creatinine is mandatory. Drugs impairing methotrexate excretion include aspirin, nonsteroidal anti-inflammatory drugs, amiodarone, omeprazole, penicillin, phenytoin, and sulfa compounds; these drugs should be stopped if possible before methotrexate administration.

D. Anthracycline Cardiotoxicity

A number of cancer chemotherapy drugs can cause cardiotoxicity. The most common class of drugs associated with cardiotoxicity is the anthracycline antibiotics, including doxorubicin, daunomycin, idarubicin, and epirubicin. They can produce acute (during administration), subacute (days to months following administration), and delayed (years following administration) cardiac toxicity. The most feared complication is the delayed development of congestive heart failure. Risk factors for this debilitating toxicity include the anthracycline cumulative dose, age over 70, previous or concurrent irradiation of the chest, preexisting cardiac disease, and concurrent administration of chemotherapy drugs such as trastuzumab. The problem is greatest with doxorubicin because this drug is the most commonly administered anthracycline due to its major role in the treatment of lymphomas, sarcomas, breast cancer, and certain other solid tumors. Patients receiving anthracyclines should have a baseline multiple-gated radio-nuclide cardiac scan (MUGA) to calculate the left ventricular-ejection fraction (LVEF). If the LVEF is > 50%, anthracyclines can be administered; if the LVEF is < 30%, these drugs should not be given. For patients with intermediate cardiac function, anthracycline dosing, if necessary, should be cautiously done with LVEF monitoring between doses. Studies of left ventricular function and endomyocardial biopsies indicate that some changes in cardiac dynamics occur in most patients by the time they have received 300 mg/m² of doxorubicin. In general, patients should not receive a total dose of doxorubicin in excess of 450 mg/m²; the dose should be lower if prior chest radiotherapy has been given. The appearance of a high resting pulse may herald the appearance of overt cardiac toxicity. Unfortunately, toxicity may be irreversible and frequently fatal at dosage levels above 550 mg/m². At lower doses (eg, 350 mg/m² of doxorubicin), the symptoms and signs of cardiac failure generally respond well to medical therapy as well as the discontinuation of anthracycline. Laboratory studies suggest that cardiac toxicity may be due to a mechanism involving the formation of intracellular free radicals in cardiac muscle. The iron chelator dexrazoxane has been approved for use as a cardioprotectant for patients receiving anthracyclines; however, some evidence suggests that the anthracycline anticancer effect may be compromised by the coadministration of dexrazoxane. In general, dexrazoxane should not be used when the goal of chemotherapy is for curative intent either in the settings of adjuvant or definitive treatment. Doxorubicin and daunomycin have been formulated as liposomal products; these drugs, approved for use in patients with Kaposi sarcoma and sometimes used in certain cancers as a substitute for conventional anthracyclines, appear to have minimal potential for cardiac toxicity.

E. Cisplatin Nephrotoxicity and Neurotoxicity

Cisplatin is effective in treating a wide range of malignancies, including testicular, bladder, lung, and ovarian cancers. Although nausea and vomiting are the side effects most commonly associated with cisplatin, the more serious side effects of nephrotoxicity and neurotoxicity must also be anticipated and aggressively managed. Patients must be vigorously hydrated prior, during, and after cisplatin administration. Both kidney function and electrolytes must be monitored. Low magnesium and potassium levels as well as hypotension can develop. The neurotoxicity is usually manifested as a peripheral neuropathy of mixed sensorimotor type and may be associated with painful paresthesias. Development of neuropathy typically occurs after cumulative doses of 300 mg/m². Otoxicity is a potentially serious manifestation of neurotoxicity and can progress to deafness. Amifostine, developed initially as a radioprotective agent and given intravenously at a dose of 910 mg/m² over 15 minutes prior to cisplatin, is used to protect against nephrotoxicity and neuropathy. Use of amifostine does not appear to compromise the antineoplastic effect of cisplatin. The second-generation platinum analog carboplatin is non-nephrotoxic, although it is myelosuppressive. In the setting of preexisting kidney disease or neuropathy, carboplatin is occasionally substituted for cisplatin.

F. Bleomycin Toxicity

Bleomycin is used for the treatment of testicular cancer, Hodgkin disease, and non-Hodgkin lymphoma. Bleomycin produces edema of the interphalangeal joints and hardening of the palmar and plantar skin. The more serious toxicities include an anaphylactic or serum sickness-like reaction and a serious or fatal pulmonary fibrotic reaction (seen especially in elderly patients receiving a total dose of over 300 units). If nonproductive cough, dyspnea, and pulmonary infiltrates develop, the drug is discontinued, and high-dose corticosteroids are instituted as well as empiric antibiotics pending cultures. Fever alone or with chills is an occasional complication of bleomycin treatment and is not an absolute contraindication to continued treatment. The fever may be avoided by intravenous premedication with hydrocortisone administration. Moreover, fever alone is not predictive of pulmonary toxicity. About 1% of patients (especially those with lymphoma) may have a severe or even fatal hypotensive reaction after the initial dose of bleomycin. In order to identify such patients, a test dose of 5 units of bleomycin is administered first with
adequate monitoring and emergency facilities available should they be needed. Patients exhibiting a hypotensive reaction should not receive further bleomycin therapy.

**PROGNOSIS**

A valuable sign of clinical improvement is the general well-being of the patient. Although this finding is a combination of subjective and objective factors and may be partly a placebo effect, it nonetheless serves as a sign of clinical improvement in assessing some of the objective observations listed above. Factors included in the assessment of general well-being are improved appetite and weight gain and increased “performance status” (eg, ambulatory versus bedridden). Evaluation of factors such as activity status enables the clinician to judge whether the net effect of chemotherapy is worthwhile palliation (see Chapter 5).

---

ACUTE INTERMITTENT PORPHYRIA

ESSENTIALS OF DIAGNOSIS

- Unexplained abdominal crisis, generally in young women.
- Acute peripheral or central nervous system dysfunction.
- Recurrent psychiatric illnesses.
- Hyponatremia.
- Porphobilinogen in the urine during an attack.

General Considerations

Though there are several different types of porphyrias, the one with the most serious consequences and the one that usually presents in adulthood is acute intermittent porphyria (AIP), which is inherited as an autosomal dominant, though it remains clinically silent in most patients who carry a mutation in HMBS. Clinical illness usually develops in women. Symptoms begin in the teens or 20s, but onset can begin after menopause in rare cases. The disorder is caused by partial deficiency of porphobilinogen deaminase activity, leading to increased excretion of aminolevulnic acid and porphobilinogen in the urine. The diagnosis may be elusive if not specifically considered. The characteristic abdominal pain may be due to abnormalities in autonomic innervation in the gut. In contrast to other forms of porphyria, cutaneous photosensitivity is absent in AIP. Attacks are precipitated by numerous factors, including drugs and intercurrent infections. Harmful and relatively safe drugs for use in treatment are listed in Table 40–1. Hyponatremia may be seen, due in part to inappropriate release of antidiuretic hormone, although gastrointestinal loss of sodium in some patients may be a contributing factor.

Clinical Findings

A. Symptoms and Signs

Patients show intermittent abdominal pain of varying severity, and in some instances it may so simulate acute abdomen as to lead to exploratory laparotomy. Because the origin of the abdominal pain is neurologic, there is an absence of fever and leukocytosis. Complete recovery between attacks is usual. Any part of the nervous system may be involved, with evidence for autonomic and peripheral neuropathy. Peripheral neuropathy may be symmetric or asymmetric and mild or profound; in the latter instance, it can even lead to quadriplegia with respiratory paralysis. Other central nervous system manifestations include seizures, psychosis, and abnormalities of the basal ganglia. Hyponatremia may further cause or exacerbate central nervous system manifestations.

B. Laboratory Findings

Often there is profound hyponatremia. The diagnosis can be confirmed by demonstrating an increased amount of porphobilinogen in the urine during an acute attack. Freshly voided urine is of normal color but may turn dark upon standing in light and air.

Most families have a different mutation in the porphobilinogen deaminase gene causing AIP. Mutations can be detected and used for presymptomatic and prenatal diagnosis.

Prevention

Avoidance of factors known to precipitate attacks of AIP—especially drugs—can reduce morbidity. Sulfonamides and barbiturates are the most common culprits; others are listed in Table 40–1 and on the Internet (www.drugs-porphyria.org). Starvation diets or prolonged fasting also cause attacks and so must be avoided. Hormonal changes during pregnancy can precipitate crises.

Treatment

Treatment with a high-carbohydrate diet diminishes the number of attacks in some patients and is a reasonable empiric gesture considering its benignity. Acute attacks may be life-threatening and require prompt diagnosis, withdrawal of the inciting agent (if possible), and treatment with analgesics and intravenous glucose and hemat. A minimum of 300 g of carbohydrate per day should be provided orally or intravenously. Electrolyte balance
**ALKAPTONURIA**

**ESSENTIALS OF DIAGNOSIS**

- Ochronosis (gray-black discoloration of connective tissue, including the sclera, ears, and cartilage).
- Characteristic radiologic changes in the spine, with radiodense intervertebral discs.
- Arthropathy.
- Urine darkens on standing.

**Clinical Findings**

**A. Symptoms and Signs**

Alkaptonuria is caused by a recessively inherited deficiency of the enzyme homogentisic acid oxidase. This acid derives from metabolism of both phenylalanine and tyrosine and is present in large amounts in the urine throughout the patient’s life. An oxidation product accumulates slowly in cartilage throughout the body, leading to degenerative joint disease of the spine and peripheral joints. Indeed, examination of patients in the third and fourth decades shows a slight darkish blue color below the skin in areas overlying cartilage, such as in the ears, a phenomenon called ochronosis. In some patients, a more severe hyperpigmentation can be seen in the sclera, conjunctiva, and cornea. Accumulation of metabolites in heart valves can lead to aortic or mitral stenosis. A predisposition to coronary artery disease may also be present. Although the syndrome causes considerable morbidity, life expectancy is reduced only modestly. Symptoms are more often attributable to spondylitis with back pain, leading to a clinical picture difficult to distinguish from that of ankylosing spondylitis, though on radiographic assessment the sacroiliac joints are not fused in alkaptonuria.

**B. Laboratory Findings**

The diagnosis is established by demonstrating homogentisic acid in the urine, which turns black spontaneously on exposure to the air; this reaction is particularly noteworthy if the urine is alkaline or when alkali is added to a specimen. Molecular analysis of the homogentisic acid oxidase gene (HGD) is available but not necessary for diagnosis.

**Prevention**

Carrier screening and prenatal diagnosis are possible by testing for genetic mutations.

requires close attention. Hematin therapy should be undertaken with full recognition of adverse consequences, especially phlebitis and coagulopathy. The intravenous dosage is up to 4 mg/kg once or twice daily. Liver transplantation may provide an option for patients with disease poorly controlled by medical therapy.

**When to Refer**

- For management of severe abdominal pain, seizures, or psychosis.
- For preventive management when a patient with porphyria contemplates pregnancy.
- For genetic counseling and molecular diagnosis.

**When to Admit**

The patient should be hospitalized when he or she has an acute attack accompanied by mental status changes, seizure, or hyponatremia.

DOWN SYNDROME

ESSENTIALS OF DIAGNOSIS

- Typical craniofacial features (flat occiput, epicanthal folds, large tongue).
- Mental retardation.
- Congenital heart disease (e.g., atrioventricular canal defects) in 50% of patients.
- Three copies of chromosome 21 (trisomy 21) or a chromosome rearrangement that results in three copies of a region of the long arm of chromosome 21.

Clinical Findings

A. Symptoms and Signs

Down syndrome is usually diagnosed at birth on the basis of the typical craniofacial features, hypotonia, and single palmar crease. Several serious problems that may be evident at birth or may develop early in childhood include duodenal atresia, congenital heart disease (especially atrioventricular canal defects), and hematologic malignancy. The intestinal and cardiac anomalies usually respond to surgery. A transient neonatal leukemia generally responds to conservative management. The incidences of both acute lymphoblastic and myeloid leukemias are increased in childhood. Intelligence varies across a wide spectrum. Many people with Down syndrome do well in sheltered workshops and group homes, but few achieve full independence in adulthood. Other frequent complications include atlanto-axial instability, celiac disease, and hypothyroidism. An Alzheimer-like dementia usually becomes evident in the fourth or fifth decade. Patients with Down syndrome who survive childhood and who develop dementia have a reduced life expectancy; on average, they live to about age 55 years.

B. Laboratory Findings

Cytogenomic analysis should always be performed—even though most patients will have simple trisomy for chromosome 21—to detect unbalanced translocations; such patients may have a parent with a balanced translocation, and there will be a substantial recurrence risk of Down syndrome in future offspring of that parent and potentially that parent’s relatives.

Prevention

Nearly 0.5% of all human conceptions are trisomic for chromosome 21. Because of increased fetal mortality, birth incidence of Down syndrome is 1 per 700 but varies from 1 per 1000 in young mothers to more than three times as frequent in women of advanced maternal age. The presence of a fetus with Down syndrome can be detected in many pregnancies in the first or early second trimester through screening maternal serum for α-fetoprotein and other biomarkers (“multiple marker screening”) and by detecting increased nuchal thickness and underdevelopment of the nasal bone on fetal ultrasound. The risk of bearing a child with Down syndrome increases exponentially with the age of the mother at conception and begins a marked rise after age 35. By age 45 years, the odds of having an affected child are as high as 1 in 40. The risk of other conditions associated with trisomy also increases, because of the predisposition of older oocytes to nondisjunction during meiosis. There is little risk of trisomy associated with increased paternal age. However, older men do have an increased risk of fathering a child with a new autosomal dominant condition. Because there are so many distinct conditions, though, the chance of fathering an offspring with any given one is extremely small.

Treatment

Duodenal atresia should be treated surgically. Congenital heart disease should be treated as in any other patient. No medical treatment has been proven to affect the intellectual capacity.

When to Refer

- For comprehensive evaluation of infants to investigate congenital heart disease, hematologic malignancy, and duodenal atresia.
- For genetic counseling of the parents.
- For signs of dementia in an adult patient.

When to Admit

An affected young patient should be hospitalized when he or she has failure to thrive, regurgitation, breathlessness, or easy bruising.

Being born with one FMR1 allele with 200 or more repeats results in mental retardation in most men, and in about 60% of women. The more repeats, the greater the likelihood that further expansion will occur during gameto-genesis; this results in anticipation, in which the disorder can worsen from one generation to the next.

**Prevention**

DNA diagnosis for the number of repeats has supplanted cytogenetic analysis for both clinical and prenatal diagnosis. This should be done on any male or female who has unexplained mental retardation. Newborn screening based on hypermethylation of the FMR1 gene is being considered as a means of early detection and intervention.

**Treatment**

No specific treatments have been developed but several based on the mouse model are in development. Valproic acid may reduce symptoms of hyperactivity and attention deficit, but standard therapies should be tried first.

**When to Refer**

- For otherwise unexplained mental retardation or learning difficulties in boys and girls.
- For otherwise unexplained tremor or ataxia in middle-aged individuals.
- For premature ovarian failure.
- For genetic counseling.

---

**GAUCHER DISEASE**

**Essentials of Diagnosis**

- Deficiency of β-glucocerebrosidase.
- Anemia and thrombocytopenia.
- Hypersplenism.
- Pathologic fractures.
Gaucher disease has an autosomal recessive pattern of inheritance. A deficiency of β-glucocerebrosidase causes an accumulation of sphingolipid within phagocytic cells throughout the body. Anemia and thrombocytopenia are common and may be symptomatic; both are due primarily to hypersplenism, but marrow infiltration with Gaucher cells may be a contributing factor. Cortical erosions of bones, especially the vertebrae and femur, are due to local infarctions, but the mechanism is unclear. Episodes of bone pain (termed "crises") are reminiscent of those in sickle cell disease. A hip fracture in a patient with a palpable spleen—especially in a Jewish person of Eastern European origin—suggests the possibility of Gaucher disease.

Two uncommon forms of Gaucher disease, called type II and type III, involve neurologic accumulation of sphingolipid and a variety of neurologic problems. Type II is of infantile onset and has a poor prognosis. Heterozygotes for Gaucher disease are at increased risk for developing Parkinson disease.

**B. Laboratory Findings**

Bone marrow aspirates reveal typical Gaucher cells, which have an eccentric nucleus and periodic acid–Schiff (PAS)-positive inclusions, along with wrinkled cytoplasm and inclusion bodies of a fibrillar type. In addition, the serum acid phosphatase is elevated. Definitive diagnosis requires the demonstration of deficient glucocerebrosidase activity in leukocytes. Hundreds of mutations have been found to cause Gaucher disease and some are highly predictive of the neuronopathic forms. Thus, mutation detection, especially in a young person, is of potential value. Only four mutations in glucocerebrosidase account for more than 90% of the disease among Ashkenazi Jews, in whom the carrier frequency is 1:15.

**Prevention**

Most clinical complications can be prevented by early institution of enzyme replacement therapy. Carrier screening, especially among Ashkenazi Jews, detects those couples at 25% risk of having an affected child. Prenatal diagnosis through mutation analysis is feasible.

**Treatment**

For many years, treatment was supportive and included splenectomy for thrombocytopenia secondary to platelet sequestration. A recombinant form of the enzyme glucocerebrosidase (imiglucerase) for intravenous administration on a regular basis now permits a reduction in total body stores of glycolipid and improvement in orthopedic and hematologic manifestations. Unfortunately, the neurologic manifestations of types II and III have not improved with enzyme replacement therapy. The major drawback is the exceptional cost of imiglucerase, which can exceed $100,000 per year for a severely affected patient. Early treatment of affected children normalizes growth and bone mineral density and improves liver and spleen size, anemia, and thrombocytopenia. Alternative or complementary therapies, including methods to reduce substrate and to provide a chaperone for a defective enzyme, are being developed. One approved medication, miglustat, does reduce the production of glucocerebrosidase in some patients, but can be poorly tolerated because of adverse effects.
reductase predisposes people to elevated fasting homocysteine levels. Both nutritional and most genetic deficiencies of these vitamins can be corrected by dietary supplementation of folic acid and, if serum levels are low, vitamins $B_6$ and $B_12$. In the United States, cereal grains are fortified with folic acid. However, therapy with $B$ vitamins and folate lowers homocysteine levels significantly but does not reduce the risk of either venous thromboembolism or complications of coronary artery disease. The role of lowering homocysteine as primary prevention for sequelae of atherosclerosis has received little direct support in clinical trials. Hyperhomocysteinemia occurs with end-stage chronic kidney disease.

### Clinical Findings

#### A. Symptoms and Signs

Homocystinuria in its classic form is caused by cystathionine $\beta$-synthase deficiency and exhibits an autosomal recessive pattern of inheritance. This results in extreme elevations of plasma and urinary homocysteine levels, a basis for diagnosis of this disorder. Homocystinuria is similar in certain superficial aspects to Marfan syndrome, since patients may have a similar body habitus and ectopia lentis is almost always present. However, mental retardation is often present in homocystinuria, and the cardiovascular events are those of repeated venous and arterial thromboses whose precise cause remains obscure. Life expectancy is reduced, especially in untreated and pyridoxine-unresponsive patients; myocardial infarction, stroke, and pulmonary embolism are the most common causes of death. This condition is diagnosed by newborn screening for hypermethioninemia; however, pyridoxine-responsive infants may not be detected. The diagnosis should be suspected in patients in the second and third decades of life who have arterial or venous thromboses without other risk factors.

#### B. Laboratory Findings

Although many mutations have been identified in the cystathionine $\beta$-synthase gene (CBS), amino acid analysis of plasma remains the most appropriate diagnostic test. Patients should be studied after they have been off folate or pyridoxine supplementation for at least 1 week. Relatively few laboratories currently provide highly reliable assays for homocysteine. Processing of the specimen is crucial to obtain accurate results. The plasma must be separated within 30 minutes; otherwise, blood cells release the amino acid and the measurement will then be artificially elevated.

#### Prevention

About 50% of patients have a form of cystathionine $\beta$-synthase deficiency that improves biochemically and clinically through pharmacologic doses of pyridoxine (50–500 mg/d) and folate (5–10 mg/d). For these patients, treatment from infancy can prevent retardation and the other clinical problems. Patients who are pyridoxine non-responders must be treated with a dietary reduction in methionine and supplementation of cysteine, also from infancy. The vitamin betaine is also useful in reducing plasma methionine levels by facilitating a metabolic pathway that bypasses the defective enzyme.

### Treatment

Patients with classic homocystinuria who have suffered venous thrombosis receive anticoagulation therapy, but there are no studies to support prophylactic use of warfarin or antiplatelet agents.

---

**KLINEFELTER SYNDROME**

#### Essentials of Diagnosis

- Males with hypogonadism and small testes.
- 47,XXY karyotype.

#### Clinical Findings

**A. Symptoms and Signs**

Boys with an extra X chromosome are normal in appearance before puberty; thereafter, they have disproportionately long legs and arms, a female escutcheon, gynecomastia, and small testes. Infertility is due to azoosperma; the seminiferous tubules are hyalinized. The diagnosis is often not made until a couple is evaluated for inability to conceive. Mental retardation is somewhat more common than in the general population. Many men with Klinefelter syndrome have learning problems. However, their intelligence usually tests within the broad range of normal. As adults, detailed psychometric testing may reveal a deficiency in executive skills. The risk of breast cancer and diabetes mellitus is much higher in men with Klinefelter syndrome than in 46,XY men.

#### B. Laboratory Findings

Low serum testosterone is common. The karyotype is typically 47,XXY.
with elongated chordae tendineae, which on occasion may rupture.

**Clinical Findings**

**A. Symptoms and Signs**

Affected patients are typically tall, with particularly long arms, legs, and digits (arachnodactyly). However, there can be wide variability in the clinical presentation. Commonly, scoliosis and anterior chest deformity, such as pectus excavatum, are found. Ectopia lentis is present in about half of patients; severe myopia is common and retinal detachment can occur. Mitral valve prolapse is seen in about 85% of patients. Aortic root dilation is common and leads to aortic regurgitation or dissection with rupture. To diagnose Marfan syndrome, people with an affected relative need features in at least two systems. People with no family history need features in the skeletal system, two other systems, and one of the major criteria of ectopia lentis, dilation of the aortic root, or aortic dissection. Patients with homocystinuria due to cystathionine synthase deficiency also have dislocated lenses; tall, disproportionate stature; and thoracic deformity. They tend to have below normal intelligence, stiff joints, and a predisposition to arterial and venous occlusive disease. Males with Klinefelter syndrome do not show the typical ocular or cardiovascular features of Marfan syndrome and are generally sporadic occurrences in the family.

**B. Laboratory Findings**

Mutations in the fibrillin gene (**FBN1**) on chromosome 15 cause Marfan syndrome. Nonetheless, no simple laboratory test is available to support the diagnosis in questionable cases because related conditions may also be due to defects in fibrillin. The nature of the **FBN1** mutation has little predictive value in terms of prognosis. The pathogenesis of Marfan syndrome involves aberrant regulation of transforming growth factor (TGF) **β** activity. Mutations in either of two receptors for TGF**β** (TGFBR1 and TGFBR2) can cause conditions that resemble Marfan syndrome in terms of aortic aneurysm and dissection and autosomal dominant inheritance.

**Prevention**

There is prenatal and presymptomatic diagnosis for patients in whom the molecular defect in fibrillin has been found.

**Treatment**

Children with Marfan syndrome require regular ophthalmologic surveillance to correct visual acuity and thus prevent amblyopia, and annual orthopedic consultation for diagnosis of scoliosis at an early enough stage so that bracing might delay progression. Patients of all ages require echocardiography at least annually to monitor aortic diameter and mitral valve function. Long-term
HEREDITARY HEMORRHAGIC TELANGIECTASIA

ESSENTIALS OF DIAGNOSIS

- Recurrent epistaxis.
- Mucocutaneous telangiectases.
- Visceral arteriovenous malformations (especially lung, liver, brain, bowel).

Clinical Findings

A. Symptoms and Signs

Hereditary hemorrhagic telangiectasia (HHT), formerly termed “Osler-Weber-Rendu syndrome,” is an autosomal dominant disorder of development of the vasculature. Epistaxis may begin in childhood or later in adolescence. Punctate telangiectases of the lips, tongue, fingers, and skin generally appear in later childhood and adolescence. Arteriovenous malformations (AVMs) can occur at any age in the brain, lungs, and liver. Bleeding from the gastrointestinal tract is due to mucosal vascular malformations and usually is not a problem until mid-adult years or later. Pulmonary AVMs can cause hypoxemia (with peripheral cyanosis, dyspnea, and clubbing) and right-to-left shunting (with embolic stroke or brain abscess). The criteria for diagnosis require presence of three of the following four features: (1) recurrent epistaxis, (2) visceral AVMs, (3) mucocutaneous telangiectases, and (4) being the near relative of a clearly affected individual. Mutation analysis can be used for presymptomatic diagnosis or exclusion of the worry of HHT.

When to Refer

- For detailed ophthalmologic examination.
- For at least annual cardiologic evaluation.
- For moderate scoliosis.
- For pregnancy in a woman with Marfan syndrome.
- For genetic counseling.

When to Admit

Any patient with Marfan syndrome in whom severe or unusual chest pain develops should be hospitalized to exclude pneumothorax and aortic dissection.

Prevention

Embolization of pulmonary AVMs with wire coils or other occlusive devices reduces the risk of stroke and brain abscess. Treatment of brain AVMs reduces the risk of hemorrhagic stroke. All patients with HHT with evidence of a pulmonary shunt should practice routine endocarditis prophylaxis (see Table 33–6). All intravenous lines (except those for transfusion of red blood cells and radiographic contrast) should have an air-filter to prevent embolization of an air bubble. Prenatal diagnosis through mutation detection is possible.

β-adrenergic blockade, titrated to individual tolerance but enough to produce a negative inotropic effect (atenolol, 1–2 mg/kg orally daily) retards the rate of aortic dilation. Several clinical trials comparing the effectiveness of atenolol and losartan, a drug that reduces activity of TGFβ, are underway. Restriction from vigorous physical exertion protects from aortic dissection. Prophylactic replacement of the aortic root with a composite graft when the diameter reaches 45–50 mm in an adult (normal: < 40 mm) prolongs life. A procedure to reimplant the patient’s native aortic valve and replace just the aneurysmal sinuses of Valsalva avoids the need for lifelong anticoagulation.

Prognosis

People with Marfan syndrome who are untreated commonly die in the fourth or fifth decade from aortic dissection or congestive heart failure secondary to aortic regurgitation. However, because of earlier diagnosis, lifestyle modifications, β-adrenergic blockade, and prophylactic aortic surgery, life expectancy has increased by several decades in the past 25 years.

β-adrenergic blockade, titrated to individual tolerance but enough to produce a negative inotropic effect (atenolol, 1–2 mg/kg orally daily) retards the rate of aortic dilation. - For genetic counseling.

When to Admit

Any patient with Marfan syndrome in whom severe or unusual chest pain develops should be hospitalized to exclude pneumothorax and aortic dissection.
Treatment

All patients in whom the diagnosis of HHT is considered should have an MRI of the brain with contrast. A contrast echocardiogram will detect most pulmonary AVMs when “bubbles” appear on the left side of the heart after 3–6 cardiac cycles. A positive contrast echocardiogram should be followed by a high-resolution CT angiogram for localization of pulmonary AVMs. Patients who have AVMs with a feeding artery of 1–2 mm diameter or greater should undergo embolization. After successful embolization of all treatable pulmonary AVMs, the CT angiogram should be repeated in 3 years. A person with a negative contrast echocardiogram should have the test repeated every 5 years.
GENERAL APPROACH TO MUSCULOSKELETAL INJURIES

ESSENTIALS OF DIAGNOSIS
- History is most important in diagnosing musculoskeletal problems.
- The mechanism of injury can explain the pathology and symptoms.
- Determine whether the injury is traumatic or atraumatic, acute or chronic, high or low velocity (greater velocity suggests more structural damage), or whether any movement aggravates or relieves pain associated with the injury.

General Considerations
Musculoskeletal problems account for about 10–20% of outpatient primary care clinical visits. Orthopedic problems can be classified as traumatic (ie, injury-related) or atraumatic (ie, degenerative or overuse syndromes) as well as acute or chronic. The mechanism of injury is usually the most helpful part of the history in determining the diagnosis. The onset of symptoms should be elicited. With acute traumatic injuries, patients typically seek medical attention within 1–6 weeks of onset. The patient should describe the exact location of symptoms, which helps determine anatomic structures that may be damaged. If the patient is vague, the clinician can ask the patient to point with one finger only to the point of maximal tenderness.

Clinical Findings
A. Symptoms and Signs
The chief musculoskeletal complaints are typically pain (most common), instability or dysfunction around the joints. Since symptoms and signs are often nonspecific, recognizing the expected combination of symptoms and physical examination signs can help facilitate the clinical diagnosis. Patients may describe symptoms of “locking” or “catching,” suggesting internal derangement in joints. Symptoms of “instability” or “giving way” suggest ligamentous injury; however, these symptoms may also be due to pain causing muscular inhibition. Constitutional symptoms of fever or weight loss, swelling with no injury, or systemic illness suggest medical conditions (such as infection, cancer, or rheumatologic disease).

Initial evaluation should follow routine trauma guidelines to rule out serious joint injury. However, typical evaluations in the clinic follow the traditional components of the physical examination and should include inspection, palpation, and assessment of range of motion and neurovascular status.

Inspection includes observation of swelling, erythema, atrophy, deformity, and (surgical) scars (remembered by the mnemonic, “SEADS”). The patient should be asked to move joints of concern (see Table 41–1). If motion is asymmetric, the clinician should assess the passive range of motion for any physical limitation.

There are special tests to assess each joint. Typically, provocative tests recreate the mechanism of injury with the goal to reproduce the patient’s pain. Stress tests apply load to ligaments of concern. Typically, 10 to 15 pounds of force should be applied when performing stress tests. Functional testing, including simple tasks performed during activities of daily living, is useful to assess injury severity.

B. Imaging
Bony pathology can be assessed using standard radiographs, although there also may be characteristic soft tissue findings. However, CT scans are the most effective method for visualizing any bony pathology, including morphology of fractures. Nuclear bone scans are now less commonly used but are still valuable for identifying stress injuries, infection, malignancy, or multisite pathology. Positron emission tomography (PET) scans are useful in identifying metastatic malignant lesions. MRI provides excellent visualization of ligaments, cartilage, and soft tissues. Gadolinium contrast can be injected as an MRI arthrogram to increase sensitivity.
of detecting certain internal derangements in joints such as labral injuries. Musculoskeletal ultrasound, where available, can be useful for identifying superficial tissue problems, including tendinopathies and synovial problems.

**C. Special Tests**

Arthrocentesis must be performed promptly to rule out an infection when acute knee pain with effusion and inflammation are present and the patient is unable to actively flex the joint. The joint fluid should be sent for cell count, crystal analysis, and culture. Arthrocentesis and joint fluid analysis demonstrating crystals can lead to the diagnosis of gout (negatively birefringent, needle-shaped crystals) or pseudogout (positively birefringent, rectangular-shaped crystals). In large, uncomfortable knee joint effusions, removal of excessive joint fluid may improve joint range of motion (flexion) and patient comfort. To avoid infecting the joint, arthrocentesis should not be performed when there is an active cellulitis or abscess overlying the joint. It is also contraindicated if there is a significant coagulopathy (INR > 3.0). Markers of inflammation such as complete blood cell count, erythrocyte sedimentation rate, and C-reactive protein, and rheumatologic tests are useful in evaluating for infectious, oncologic, or rheumatologic processes. Electrodiagnostic studies such as electromyography and nerve conduction studies are useful when there are neurologic concerns; they can also help with prognostication in chronic conditions.

**Treatment**

While most outpatient musculoskeletal problems are best treated conservatively, the first consideration is whether there is an immediate surgical need. Surgical treatment is chosen when the outcome promises better health, restoration of function, and improved quality of life. During surgery, the musculoskeletal problem is usually repaired, removed, realigned, reconstructed, or replaced (eg, joint replacement).

If surgery is not immediately indicated, conservative treatment in the outpatient setting usually includes modification of activities, ice, compression, and elevation (remembered by the mnemonic, “MICE”). Controlling pain is an early concern for most patients. Commonly prescribed medications are analgesics (nonsteroidal anti-inflammatory drugs [NSAIDs], acetaminophen, or opioids). Other medications that may also be prescribed, albeit less commonly, are muscle relaxants or co-analgesics for neuropathic pain (which include the calcium channel α₂-δ ligands [eg, gabapentin] or tricyclic antidepressants). Topical medications, such as capsaicin cream or patch, lidocaine patches, and NSAID patches, can help provide superficial local pain relief.

Immobilization by casting, slings, and braces is helpful to protect an injured limb. Crutches are useful to reduce weight bearing. Rehabilitation and physical therapy are frequently needed. Other modalities commonly used by patients include chiropractic manipulation, massage therapy, acupuncture, and osteopathy.

**When to Refer**

Indications for emergency referral (immediate)
- Neurovascular injury.
- Fractures (open, unstable).
- Unreduced joint dislocation.
- Septic arthritis.

Indications for urgent referral (within 7 days)
- Fractures (closed, stable).
- Reduced joint dislocation.
- “Locked” joint (inability to fully extend a joint due to mechanical derangement, usually a loose body or torn cartilage).
- Tumor.

Indications for early orthopedic assessment (2–4 weeks)
- Motor weakness (neurologic).
- Constitutional symptoms (eg, fever not due to septic arthritis, weight loss).
- Multiple joint involvement.

Indications for routine orthopedic assessment (for further management)
- Failure of conservative treatment (persistent symptoms > 3 months).
- Persistent numbness and tingling in an extremity.

**SHOULDER**

1. **Subacromial Impingement Syndrome**

> **ESSENTIALS OF DIAGNOSIS**

- Shoulder pain with overhead motion.
- Night pain with sleeping on shoulder.
- Pain with internal rotation.
- Numbness and pain radiation below the elbow are usually due to cervical spine disease.

> **General Considerations**

The chief complaints for shoulder problems are usually pain, instability, weakness, or loss of range of motion. With any shoulder problem, it is important to establish the patient’s hand dominance, occupation, and recreational activities because shoulder injuries may present differently depending on the demands placed on the shoulder joint.
For example, baseball pitchers with impingement syndrome may complain of pain while throwing. Alternatively, elders with even full thickness rotator cuff tears may not complain of any pain because the demands on the joint are low.

The subacromial impingement syndrome describes a collection of diagnoses that cause mechanical inflammation in the subacromial space. Causes of impingement syndrome can be related to muscle strength imbalances, poor scapula control, rotator cuff tears, and subacromial bone spurs.

Clinical Findings

A. Symptoms and Signs

Shoulder problems classically present with one or more of the following: pain with overhead activities, nocturnal pain with sleeping on the shoulder, or pain on internal rotation (eg, putting on a jacket or bra). On inspection, there may be appreciable atrophy in the supraspinatus or infraspinatus fossa. The patient with impingement syndrome can have mild scapula winging or “dyskinesis.” The patient often has a rolled-forward shoulder posture or head-forward posture. On palpation, the patient can have tenderness over the anterolateral shoulder at the edge of the greater tuberosity. The patient may lack full active range of motion (Table 41–1) but should have preserved passive range of motion. Impingement symptoms can be elicited with the Neer and Hawkins impingement signs (Table 41–1).

B. Imaging

The following four radiographic views should be ordered to evaluate subacromial impingement syndrome: the anteroposterior scapula, the anteroposterior acromioclavicular joint, the lateral scapula (scapular Y), and the axillary lateral. The anteroposterior scapula view can rule out glenohumeral joint arthritis. The anteroposterior acromioclavicular view evaluates the acromioclavicular joint for inferior spurs. The scapula Y view evaluates the acromial shape, and the axillary lateral view visualizes the glenohumeral joint as well and for the presence of os acromiale.

MRI of the shoulder may demonstrate full or partial thickness tears or tendinosis. Ultrasound evaluation may demonstrate thickening of the rotator cuff tendons and tendinosis. Tears may also be visualized, although it is more difficult to identify partial tears from small full thickness on ultrasound than on MRI.

Treatment

A. Conservative

The first-line treatment for impingement syndrome is usually a conservative approach with education, activity modification, and physical therapy exercises. Impingement syndrome can be caused by muscle weakness or tear. Rotator cuff muscle strengthening can alleviate weakness or pain, unless the tendons are seriously compromised, which may cause more symptoms. Physical therapy is directed at rotator cuff muscle strengthening, scapula stabilization, and postural exercises. There is no strong evidence supporting the effectiveness of ice and NSAID therapy. In a 2004 Cochrane review, corticosteroid injections produced slightly better relief of symptoms in the short-term when compared with placebo. Most patients respond well to conservative treatment.

B. Surgical

Procedures include arthroscopic acromioplasty with coracoacromial ligament release, bursectomy, or debridement or repair of rotator cuff tears.

When to Refer

• Failure of conservative treatment over 3 months.
• Young and active patients with impingement due to full thickness rotator cuff tears.

2. Rotator Cuff Tears

General Considerations

Rotator cuff tears can be caused by acute injuries related to falls on an outstretched arm or to pulling on the shoulder. It can also be related to chronic repetitive injuries with overhead movement and lifting. Partial rotator cuff tears are one of the major reasons for impingement syndrome. Full thickness rotator cuff tears are usually more symptomatic and may require surgical treatment. The most commonly torn tendon is the supraspinatus.

Clinical Findings

A. Symptoms and Signs

Most patients complain of weakness or pain with overhead movement. Night pain is also a common complaint. The clinical findings with rotator cuff tears include those of the impingement syndrome except that with full-thickness rotator cuff tears there may be more obvious weakness noted with light resistance testing of specific rotator cuff muscles. Supraspinatus tendon strength is tested with

<tbody>
<tr>
<td><strong>Inspection</strong></td>
<td>Check the patient’s posture and “SEADS” (swelling, erythema, atrophy, deformity, surgical scars).</td>
</tr>
<tr>
<td><strong>Palpation</strong></td>
<td>Include important landmarks: acromioclavicular (AC) joint, long head of biceps tendon, coracoid, and greater tuberosity (supraspinatus insertion).</td>
</tr>
<tr>
<td><strong>Range of motion testing</strong></td>
<td>Check range of motion actively (patient performs) and passively (clinician performs).</td>
</tr>
<tr>
<td><strong>Flexion</strong></td>
<td>Move the arm forward as high as possible in the sagittal plane.</td>
</tr>
<tr>
<td><strong>External rotation</strong></td>
<td>Check the patient’s elbow touching their body so that external rotation occurs predominantly at the glenohumeral joint.</td>
</tr>
</tbody>
</table>
The patient is asked to reach the thumbs as high as possible behind the spine on each side. The clinician can record the highest spinous process that the individual can reach on each side (iliac crest = L4, inferior angle of scapula = T8).

**Rotator cuff strength testing**

**Supraspinatus (open can) test**

Perform resisted shoulder abduction at 90 degrees with slight forward flexion to around 45 degrees to test for supraspinatus tendon strength ("open can" test), or with shoulder abduction at 30 degrees and flexion to 30 degrees ("empty can" test).

**External rotation**

The patient resists by externally rotating the arms with elbows at his or her side.

(continued)
resisted shoulder abduction at 90 degrees with slight forward flexion to around 45 degrees (“open can” test) (Table 41–1). Infraspinatus/teres minor strength is tested with resisted shoulder external rotation with shoulder at 0 degrees abduction, elbow by side (Table 41–1). Subscapularis strength is tested with the “lift-off” or “belly-press” tests (Table 41–1). The affected patient usually also has positive Neer and Hawkins impingement tests.

B. Imaging

Recommended radiographs are very similar to impingement syndrome: anteroposterior scapula (glenohumeral), axillary lateral, supraspinatus outlet, and anteroposterior acromioclavicular joint views. The anteroposterior scapula view is useful in visualizing rotator cuff tears because degenerative changes can appear between the acromion and greater tuberosity of the shoulder. Axillary lateral views show superior elevation of the humeral head in relation to the center of the glenoid. Supraspinatus outlet views allow evaluation of the shape of the acromion. High-grade acromial spurs are associated with a higher incidence of rotator cuff tears. The anteroposterior acromioclavicular joint view evaluates for the presence of acromioclavicular joint arthritis, which can mimic rotator cuff tears, and for spurs that can cause rotator cuff injuries.

MRI is the best method for visualizing rotator cuff tears. The MR arthrogram can show partial or small (< 1 cm) rotator cuff tears. For patients who cannot undergo MRI testing or when postoperative artifacts limit MRI evaluations, ultrasonography can be helpful.

Treatment

Partial rotator cuff tears may heal with scarring. Most partial rotator cuff tears can be treated with physical therapy and scapular and rotator cuff muscle strengthening. Physical therapy can strengthen the remaining muscles to compensate for loss of strength. Physical therapy is also an option for older sedentary patients. On the contrary, full-thickness rotator cuff tears do not heal well and have a tendency to progress with time. Most young active patients with acute, full-thickness tears should be treated with operative fixation.

Subscapularis tendon injuries warrant different treatment. Full-thickness subscapularis tendon tears should undergo surgical repair as they usually lead to premature osteoarthritis of the shoulder.
When to Refer

- Young and active patients with full thickness rotator cuff tears.
- Partial tears with > 50% involvement and with significant pain.
- Older and sedentary patients with full-thickness rotator cuff tears who have not responded to nonoperative treatment.
- Full thickness subscapularis tears.

3. Shoulder Dislocation & Instability

ESSENTIALS OF DIAGNOSIS

- Most dislocations (95%) are in the anterior direction.
- Pain and apprehension with an unstable shoulder that is abducted and externally rotated.
- Acute shoulder dislocations should be reduced as quickly as possible, using manual relocation techniques if necessary.

General Considerations

The shoulder is a ball and socket joint, similar to the hip. However, the bony contours of the shoulder bones are much different than the hip. Overall, the joint has much less stability than the hip, allowing greater movement and action. Stabilizing the shoulder joint relies heavily on rotator cuff muscle strength and also scapular control. Ninety five percent of the shoulder dislocations/instability occur in the anterior direction. Dislocations usually are caused by a fall on an outstretched and abducted arm. Patients complain of pain and feeling of instability when the arm is in the abducted and externally rotated position. Posterior dislocations are usually caused by falls from a height, epileptic seizures, or electric shocks. Traumatic shoulder dislocation can lead to instability. The rate of repeated dislocation is directly related to the patient’s age: patients age 21 years or younger have a 70–90% risk of redislocation, whereas patients age 40 years or older have a much lower rate (20–30%). Ninety percent of young active individuals who had traumatic shoulder dislocation have labral injuries often described as Bankart lesions when the anterior inferior labrum is torn, which can lead to continued instability. Older patients (over age 55 years) are more likely to have rotator cuff tears or fractures following dislocation. Atraumatic shoulder dislocations are usually caused by intrinsic ligament laxity or repetitive microtrauma leading to joint instability. This is often seen in swimmers, gymnasts, and pitchers as well as other athletes involved in overhead and throwing sports.

Clinical Findings

A. Symptoms and Signs

For acute traumatic dislocations, patients usually have an obvious deformity with the humeral head dislocated anteriorly. The patient holds the shoulder and arm in an externally rotated position. The patient complains of acute pain and deformity that are improved with manual relocation of the shoulder. Reductions are usually performed in the emergency department. Even after reduction, the patient will continue to have limited range of motion and pain especially following a first-time shoulder dislocation.

Patients with recurrent dislocations can have less pain with subsequent dislocations. Posterior dislocations can be easily missed because the patient usually holds the shoulder and arm in an internally rotated position, which makes the shoulder deformity less obvious. Patients complain of difficulty pushing open a door.

Atraumatic shoulder instability is usually well tolerated with activities of daily living. Patients usually complain of a “sliding” sensation during exercises or strenuous activities such as throwing. Such dislocations may be less symptomatic and can often undergo spontaneous reduction of the shoulder with pain resolving within days after onset. The clinical examination for shoulder instability includes the apprehension test (Table 41–1), the load and shift test (Table 41–1) and the O’Brien test (Table 41–1). Most patients with persistent shoulder instability have preserved range of motion.

B. Imaging

Radiographs for acute dislocations should include a standard trauma series of anteroposterior and axillary lateral scapula (glenohumeral) views to determine the relationship of the humerus and the glenoid and to rule out fractures. Orthogonal views are used to identify a posterior shoulder dislocation, which can be missed easily with one anteroposterior view of the shoulder. An axillary lateral view of the shoulder can be safely performed even in the acute setting of a patient with a painful shoulder dislocation. For chronic injuries or symptomatic instability, these recommended radiographic views are helpful to identify bony injuries and Hill-Sachs lesions (indentated compression fractures at the posterior-superior part of the humeral head associated with anterior shoulder dislocation). MRI is commonly used to show soft tissue injuries to the labrum and to visualize associated rotator cuff tears. MRI arthrograms better identify labral tears and ligamentous structures.

Treatment

For acute dislocations, the shoulder should be reduced as soon as possible. The Stimson procedure is the least
traumatic method and is quite effective. The patient lies prone with the dislocated arm hanging off the examination table with a weight applied to the wrist to provide traction for 20–30 minutes. Afterward, gentle mediolateral mobilization can be applied manually to assist the reduction. The shoulder can also be reduced with axial “traction” on the arm with “counter-traction” along the trunk. The patient should be sedated and relaxed. The shoulder can then be gently internally and externally rotated to guide it back into the socket.

Initial treatment of acute shoulder dislocations should include sling immobilization for 2–4 weeks along with pendulum exercises. Early physical therapy can be used to maintain range of motion and strengthening of rotator cuff muscles. Patients can also modify their activities to avoid active and risky sports. For patients with a traumatic incident and unilateral shoulder dislocation, a Bankart lesion is commonly present (remembered by the mnemonic, “TUBS”) and surgical treatment is often required.

The treatment of atraumatic shoulder instability is different than traumatic shoulder instability. Patients with chronic, recurrent shoulder dislocations should be managed with physical therapy and a regular maintenance program, consisting of scapular stabilization and postural and rotator cuff strengthening exercises. Activities may need to be modified. In patients with an atraumatic, multidirectional, bilateral shoulder instability, rehabilitation is the mainstay for treatment; inferior capsular shift surgery is rarely required (remembered by the mnemonic, “AMBRI”).

### When to Refer

- Patients who are at risk for second dislocation, such as young patients, certain jobholders (eg, police officers, fire fighters, and rock climbers) to avoid recurrent dislocation or dislocation while at work.
- Patients who have not responded to conservative approach or who have chronic instability.

### General Considerations

Adhesive capsulitis (“frozen shoulder”) is seen commonly in patients 40- to 65-years-old. It is more commonly seen in women than men, especially in perimenopausal women or in patients with endocrine disorders, such as diabetes mellitus or thyroid disease. Adhesive capsulitis is a self-limiting but very debilitating disease.

### Clinical Findings

#### A. Symptoms and Signs

Patients usually present with a painful shoulder that has a limited range of motion with both passive and active movements. A useful clinical sign is limitation of movement of external rotation with the elbow by the side of the trunk (Table 41–1). Strength is usually normal but it can appear diminished when the patient is in pain.

There are three phases: the inflammatory phase, the “freezing” phase, and the “thawing” phase. During the inflammatory phase, which usually lasts 4–6 months, patients complain of a very painful shoulder without obvious clinical findings to suggest trauma, fracture, or rotator cuff tear. During the “freezing” phase, which also usually lasts 4–6 months, the shoulder becomes stiffer and stiffer even though the pain is improving. The “thawing” phase can take up to a year as the shoulder slowly regains its motion. The total duration of an idiopathic frozen shoulder is usually about 24 months; it can be much longer for patients who have trauma or an endocrinopathy.

#### B. Imaging

Standard anteroposterior, axillary, and lateral glenohumeral radiographs are useful to rule out glenohumeral arthritis, which can also present with limited active and passive range of motion. However, adhesive capsulitis is usually a clinical diagnosis, and it does not need an extensive diagnostic work-up.

#### Treatment

Adhesive capsulitis is caused by acute inflammation of the capsule followed by scarring and remodeling. During the acute “freezing” phase, NSAIDs and physical therapy are recommended to maintain motion. There is also evidence of short-term benefit from intra-articular corticosteroid injection or oral prednisone. One study demonstrated improvement at 6 weeks but not 12 weeks following 30 mg of daily prednisone for 3 weeks. During the “freezing” phase, the shoulder is less painful but remains stiff. Anti-inflammatory medication is not as helpful during the “thawing” phase as it is during the “freezing” phase, and the shoulder symptoms usually resolve with time. Surgical treatments include manipulation under anesthesia and arthroscopic release.

#### When to Refer

- When the patient does not respond after more than 6 months of conservative treatment.
- When there is no progress or worsening range of motion over 3 months.

SPINE PROBLEMS

1. Low Back Pain

ESSENTIALS OF DIAGNOSIS

- The cause of back pain may be categorized by pain on flexion versus pain on extension.
- Nerve root impingement is suspected when pain is leg-dominant rather than back-dominant.
- Alarming signs for serious spinal disease include unexplained weight loss, failure to improve with treatment, severe pain for more than 6 weeks, and night or rest pain.
- The cauda equina syndrome often presents with bowel or bladder symptoms (or both) and is an emergency.

General Considerations

Low back pain is the most common cause of disability for patients under the age of 45 and is the second most common cause for primary care visits. The annual prevalence of low back pain is 15–45%, and the annual cost in the United States is over $50 billion. Approximately 80% of episodes of low back pain resolve within 2 weeks and 90% resolve within 6 weeks. The exact cause of the low back pain is often difficult to diagnose; its cause is often multifactorial, although there are usually degenerative changes in the lumbar spine.

Alarming symptoms for back pain caused by cancer include unexplained weight loss, failure to improve with treatment, pain for more than 6 weeks, and pain at night or rest. History of cancer and age > 50 years are other risk factors for malignancy. Alarming symptoms for infection include fever, rest pain, recent infection (urinary tract infection, cellulitis, pneumonia), or history of immunocompromise or injection drug use. The cauda equina syndrome is suggested by urinary retention or incontinence, saddle anesthesia, decreased anal sphincter tone or fecal incontinence, bilateral lower extremity weakness, and progressive neurologic deficits. Risk factors for back pain due to vertebral fracture include use of corticosteroids, age > 70 years, history of osteoporosis, recent significant trauma, or very severe focal pain. Back pain may also be the presenting symptom in other serious medical problems, including abdominal aortic aneurysm, peptic ulcer disease, kidney stones, and pancreatitis.

Clinical Findings

A. Symptoms and Signs

The physical examination is best done with the patient in the standing, sitting, supine, and then prone positions to avoid frequent repositioning of the patient. In the standing position, the patient’s posture can be observed. Commonly encountered spinal asymmetries include scoliosis, thoracic kyphosis, and lumbar hyperlordosis. The active range of motion of the lumbar spine can be assessed. The common directions include flexion, rotation, and extension. The one-leg standing extension test assesses for pain as the patient stands on one leg while extending the spine. A positive test can be caused by pars interarticularis fractures (spondylolysis or spondylolisthesis) or facet joint arthritis, although sensitivity and specificity of the test is limited.

In the sitting position, the major muscles in the lower extremities are assessed for weakness by eliciting a resisted isometric contraction for approximately 5 seconds. It is important to compare the strength bilaterally to detect subtle muscle weakness, including hip flexors (L1–2 nerve roots), knee extensors or quadriceps (L3), ankle dorsiflexors (L4–L5), first toe extensor or extensor hallucis longus (L5), knee flexors or hamstrings (S1), ankle plantar-flexors or calf muscles (S1), and hip extensors (S1). Sensory testing to light touch is done next for the following areas: groin (L1 nerve root), thigh (L2, knee (L3), lateral shin and medial ankle (L4), first dorsal web space of the foot between first and second toes (L5), lateral foot (S1), back of the thigh (S2), and perianal area (S3, S4, S5). Knee (femoral nerve L2–4), ankle (deep peroneal nerve L4–L5), and Babinski (sciatric nerve L5–S1) reflexes can be checked with the patient sitting.

In the supine position, the hip should be evaluated for range of motion, focusing on internal rotation. The straight leg raise test puts traction and compression forces on the lower lumbar nerve roots (Table 41–2).

Finally, in the prone position, the clinician can carefully palpate each level of the spine and sacroiliac joints for tenderness. A rectal examination is required if the cauda equina syndrome is suspected. Superficial skin tenderness to a light touch over the lumbar spine, overreaction to maneuvers in the regular back examination, low back pain on axial loading of spine in standing, inconsistency in the straight leg raise test or on the neurologic examination suggest nonorthopedic causes for the pain or malingering.

B. Imaging

In the absence of alarming “red flag” symptoms suggesting infection, malignancy, or cauda equina syndrome, diagnostic imaging, including radiographs, is not typically recommended in the first 6 weeks. If done, radiographs of the lumbar spine should include anteroposterior and lateral views. Oblique views can be useful if the neuroforamina or lesions need to be visualized. MRI is the method of choice in the evaluation of symptoms not responding to conservative treatment or in the presence of red flags of serious conditions.
C. Special Tests

Electromyography or nerve conduction studies may be useful in assessing patients with possible nerve root symptoms lasting longer than 6 weeks; back pain may or may not also be present. These tests are usually not necessary if the diagnosis of radiculopathy is clear.

<table>

Cross-over pain, where sciatica symptoms occur down the opposite leg during a straight leg raise, usually indicates a large disk herniation.</td>
</tr>
</tbody>
</table>

D. Treatment

A. Conservative

Nonpharmacologic treatments are key in the management of low back pain. Education alone improves patient satisfaction with recovery and recurrence. Patients require information and reassurance when diagnostic procedures are not necessary. Discussion must include reviewing safe and effective methods of symptom control as well as how to decrease the risk of recurrence with proper lifting techniques, abdominal wall/core strengthening, weight loss, and smoking cessation. Strengthening and stabilization effectively reduce pain and functional limitation compared with usual care.

Physical therapy exercise programs can be tailored to the patient’s symptoms and pathology. Spinal manipulation has short-term benefits if therapy is started within 6 weeks of onset of low back pain without radiculopathy. Heat and cold treatments have not shown any long-term benefits but may be used for symptomatic treatment. The efficacy of transcutaneous electrical nerve stimulation (TENS), back braces, physical agents, and acupuncture is unproven. Improvements in posture, core stability strengthening, physical conditioning, and modifications of activities to decrease physical strain are keys for ongoing management.

NSAIDs are effective in the early treatment of low back pain (see Chapter 20). There is limited evidence that muscle relaxants can provide short-term relief; since these medications have addictive potential, they should be used with care. Muscle relaxants are best used if there is true muscle spasm that is painful rather than simply a protective response. Opioids may be necessary to alleviate pain immediately. Treatment of more chronic neuropathic pain with gabapentin and tricyclic antidepressants may be helpful.

B. Surgical

Surgical indications for back surgery include cauda equina syndrome, ongoing morbidity with no response to > 6 months of conservative treatment, cancer, infection, or severe spinal deformity. Prognosis is improved when there is an anatomic lesion that can be corrected and symptoms are neurologic. Spinal surgery has limitations. Patient selection is very important and the specific surgery recommended should have very clear indications. Patients should understand that surgery can improve their pain but is unlikely to cure it. Surgery is not generally indicated for radiographic abnormalities alone when the patient is asymptomatic. Depending on the surgery performed, possible complications include persistent pain; surgical site pain, especially if bone grafting is needed; infection; neurologic damage; non-union; cutaneous nerve damage; implant failure; deep venous thrombosis; and death.

When to Refer

- Patients with the cauda equina syndrome.
- Patients with cancer, infection, or severe spinal deformity.
- Patients who have not responded to conservative treatment.
2. Spinal Stenosis

**ESSENTIALS OF DIAGNOSIS**

- Pain is usually worse with back extension and relieved by sitting.
- Occurs in older patients.
- May present with neurogenic claudication symptoms with walking.

**General Considerations**

Osteoarthritis in the lumbar spine can cause narrowing of the spinal canal. A large disk herniation can also cause stenosis and compression of neural structures or the spinal artery resulting in "claudication" symptoms with ambulation. The condition usually affects patients aged 50 years or older.

**Clinical Findings**

Patients report pain that worsens with extension. They describe reproducible single or bilateral leg symptoms that are worse after walking several minutes and that are relieved by sitting (termed “neurogenic claudication”). On examination, patients often exhibit limited extension of the lumbar spine, which may reproduce the symptoms radiating down the legs. A thorough neurovascular examination is recommended.

**Treatment**

Flexion-based exercises as demonstrated by a physical therapist can help relieve symptoms. Spinal or facet joint corticosteroid injections can also reduce pain symptoms. Spinal decompression (widening the spinal canal or laminectomy), nerve root decompression (freeing a single nerve), and spinal fusion (joining the vertebra to eliminate motion and diminish pain from the arthritic joints) have not been shown to be superior to natural history, placebo treatment, or conservative management of degenerative lumbar disk disease (spondylosis). Some evidence suggests that instrumentation (adding surgical hardware to a spinal fusion) leads to a higher fusion rate, but there is no evidence that it makes any difference to clinical outcomes.

**When to Refer**

- If a patient exhibits radicular or claudication symptoms > 12 weeks.
- MRI or CT confirmation of significant spinal stenosis.

3. Lumbar Disk Herniation

**ESSENTIALS OF DIAGNOSIS**

- Pain with back flexion or prolonged sitting.
- Radicular pain with compression of neural structures.
- Lower extremity numbness.
- Lower extremity weakness.

**General Considerations**

Lumbar disk herniation is usually due to bending or heavy loading (eg, lifting) with the back in flexion, causing herniation or extrusion of disk contents (nucleus pulposus) into the spinal cord area. However, there may not be an inciting incident. Disk herniations usually occur from degenerative disk disease (desiccation of the annulus fibrosus) in patients between 30- and 50-years-old. The L5–S1 disk is affected in 90% of cases. Compression of neural structures, such as the sciatic nerve, causes radicular pain. Severe compression of the spinal cord can cause the cauda equina syndrome, a surgical emergency (see above).

**Clinical Findings**

**A. Symptoms and Signs**

Discogenic pain typically is localized in the low back at the level of the affected disk and is worse with activity. "Sciatica" causes electric shock-like pain radiating down the posterior aspect of the leg often to below the knee. Symptoms usually worsen with back flexion such as bending or sitting for long periods (eg, driving). A significant disk herniation can cause numbness and weakness, including weakness with plantar flexion of the foot (L5/S1) or dorsiflexion of the toes (L4/L5). The cauda equina syndrome should be ruled out if the patient complains of perianal numbness or bowel or bladder incontinence.

**B. Imaging**

Plain radiographs are helpful to assess spinal alignment (scoliosis, lordosis), disk space narrowing, and osteoarthritis...
changes. MRI is the best method to assess the level and morphology of the herniation and is recommended if surgery is planned.

**Treatment**

For an acute exacerbation of pain symptoms, bed rest is appropriate for up to 48 hours. Otherwise, first-line treatments include modified activities; NSAIDs and other analgesics; and physical therapy, including core stabilization and McKenzie exercises. Epidural and transformaminal corticosteroid injections can be beneficial, especially in relieving acute radicular pain, although the benefit tends to last only 3 months. These injections may be effective in delaying surgery for chronic low back pain. Oral prednisone can reduce inflammation and is useful in reducing symptoms of acute sciatica; the initial dose is approximately 1 mg/kg once daily with tapering doses over 10 days. Co-analgesics for neuropathic pain, such as the calcium channel α2-δ ligands (ie, gabapentin, pregabalin) or tricyclic antidepressants, may be helpful (see Chapter 5).

A large, ongoing trial has shown that patients who underwent surgery for a lumbar disk herniation achieved greater improvement than conservatively treated patients in all primary and secondary outcomes except return to work status after 4 year follow-up.

**When to Refer**

- Cauda equina syndrome.
- Progressive worsening of neurologic symptoms.
- Loss of motor function (sensory losses can be followed in the outpatient clinic).

**General Considerations**

Most neck pain, especially in older patients, is due to mechanical degeneration involving the cervical disks, facet joints, and ligamentous structures and may occur in the setting of degenerative changes at other sites as well. Pain can also come from the supporting neck musculature, which often acts to protect the underlying neck structures. Posture is a very important factor, especially in younger patients. Many work-related neck symptoms are due to poor posture and repetitive motions over time. Acute injuries can also occur secondary to trauma. For example, whiplash occurs in 15–40% of motor vehicle accidents, with chronic pain developing in 5–7%. Neck fractures are serious traumatic injuries acutely and can lead to osteoarthritis in the long term. Ultimately, many degenerative conditions of the neck result in cervical canal stenosis or neural foraminal stenosis, sometimes affecting underlying neural structures. Cervical radiculopathy can cause neurologic symptoms in the upper extremities usually deriving from disease of the C5–C7 disks. Patients with neck pain may report associated headaches and shoulder pain. Thoracic outlet syndrome, in which there is mechanical compression of the brachial plexus and neurovascular structures with overhead positioning of the arm, should be considered in the differential diagnosis of neck pain.

**Clinical Findings**

**A. Symptoms and Signs**

The patient’s posture should be assessed, checking for shoulder rolled forward or head forward posture as well as scoliosis in the thoracolumbar spine. Patients with discoigenic neck pain often complain of pain with flexion, which causes cervical disks to herniate posteriorly. Extension of the neck usually affects the neural foraminal and facet joints of the neck. Rotation and lateral flexion of the cervical spine should be measured both to the left and the right. A detailed neurovascular examination of the upper extremities should be performed, including sensory input to light touch and temperature; motor strength testing, especially the hand intrinsic muscles (thumb extension strength [C8–T1]); and upper extremity reflexes (biceps, triceps, brachioradialis). True cervical radiculopathy symptoms should match an expected dermatomal or myotomal distribution. The **Spurling test** involves asking the patient to rotate and extend the neck to one side (Table 41–3). The clinician can apply a gentle axial load to the neck. Reproduction of the cervical radiculopathy symptoms is a positive sign of nerve root compression. Palpation of the neck is best performed with the patient in the supine position where the clinician can palpate each level of the cervical spine with the muscles of the neck relaxed.

**B. Imaging**

Radiographs of the cervical spine can assist in determining the area of degenerative changes. Useful views include the anteroposterior and lateral view of the cervical spine. The
odontoid view is usually added to rule out traumatic fractures and congenital abnormalities. Oblique views of the cervical spine can provide further information about arthritis changes and assess the neural foramina for narrowing.

CT scanning is the most useful method if bony abnormalities, such as fractures, are suspected. MRI is the best method to assess the cervical spine since the soft tissue structures (such as the disks, spinal cord, and nerve roots) can be evaluated. If the patient has signs of cervical radiculopathy with motor weakness, these more sensitive imaging modalities should be obtained urgently.

### Treatment

A course of neck stretching, strengthening and postural exercises in physical therapy have demonstrated benefit in relieving symptoms. Chiropractic manual manipulation and mobilization can provide short-term benefit for mechanical neck pain. Although the rate of complications is low (5–10/million manipulations), care should be taken whenever there are neurologic symptoms present. Specific patients may respond to use of home cervical traction. A soft cervical collar can be useful for short-term use (up to 1–2 weeks) in acute neck injuries. NSAIDs are commonly used and opioids may be needed in cases of severe neck pain. Muscle relaxants (eg, cyclobenzaprine 5–10 mg orally three times daily) can be used short-term if there is muscle spasm or as a sedative to aid in sleeping. Acute radicular symptoms can be treated with neuropathic medications (eg, gabapentin 300–1200 mg orally three times daily), and a short course of oral prednisone (5–10 days) can be considered (starting at 1 mg/kg). Cervical foraminal or facet joint injections can also reduce symptoms. Surgeries are successful in reducing neurologic symptoms in 80–90% of cases but are still considered as treatments of last resort.

#### When to Refer

- Patients with severe symptoms with motor weakness.
- Surgical decompression surgery if the symptoms are severe and there is identifiable, correctable pathology.

### UPPER EXTREMITY

#### 1. Lateral & Medial Epicondylosis

### ESSENTIALS OF DIAGNOSIS

- Tenderness over the lateral or medial epicondyle.
- Diagnosis of tendinopathy is confirmed by pain with resisted strength testing and passive stretching of the affected tendon and muscle unit.
- Physical therapy and activity modification are more successful than anti-inflammatory treatments.

#### General Considerations

Tendinopathy involving the wrist extensors, flexors, and pronators are very common complaints. The underlying mechanism is chronic repetitive overuse causing microtrauma at the tendon insertion, although acute injuries can occur as well if the tendon is strained due to excessive loading. The traditional term “epicondylitis” is a misnomer because histologically tendinosis or degeneration in the tendon is seen rather than acute inflammation. Therefore, these entities should be referred to as “tendinopathy” or “tendinosis." Lateral epicondylitis involves the wrist extensors, especially the extensor carpi radialis brevis. This is usually caused by lifting with the wrist and the elbow extended. Medial epicondylitis involves the wrist flexors and most commonly the pronator teres tendon. Ulnar neuropathy and cervical radiculopathy should be considered in the differential diagnosis.

#### Clinical Findings

##### A. Symptoms and Signs

For lateral epicondylitis, the patient describes pain with the arm and wrist extended. For example, common complaints include pain while shaking hands, lifting
objects, using a computer mouse, or hitting a backhand in tennis ("tennis elbow"). Medial epicondylitis presents with pain during motions in which the arm is repetitively pronated or the wrist is flexed. This is also known as "golfer’s elbow" due to the motion of turning the hands over during the golf swing. On examination, tenderness directly over the epicondyle is present, especially over the posterior aspect where the tendon insertion occurs. The proximal tendon and musculotendinous junction can also be sore. To confirm that the pain is due to tendinopathy, pain can be reproduced over the epicondyle with resisted wrist extension and third digit pronation and wrist flexion for medial epicondylitis. The pain is also often reproduced with passive stretching of the affected muscle groups, which can be performed with the arm in extension. It is useful to check the ulnar nerve (located in a groove at the posteromedial elbow) for tenderness as well as to perform a Spurling test for cervical radiculopathy.

B. Imaging

Radiographs are often normal, although a small traction spur may be present in chronic cases (enthesopathy). Diagnostic investigations are usually unnecessary, unless the patient does not improve after up to 3 months of conservative treatment. At that point, a patient who demonstrates significant disability due to the pain should be assessed with an MRI or ultrasound. Ultrasound and MRI can visualize the tendon and confirm tendinosis or tears.

Treatment

Treatment is usually conservative, including patient education regarding activity modification and management of symptoms. Ice and NSAIDs can help with pain. The most important steps are to begin a good stretching program followed by strengthening exercises. Counterforce elbow braces might provide some symptomatic relief, although there is no published evidence to support their use. If the patient has severe or long-standing symptoms, a course of physical therapy should be performed. Corticosteroid injection offers some short-term improvement. However, physical therapy and rehabilitative exercises are still the mainstays of treatment. Treatments such as extracorporeal shock wave therapy and injectable medications other than corticosteroids have not shown clear long-term benefit.

When to Refer

Patients not responding to 6 months of conservative treatment should be referred for surgical debridement or repair of the tendon.

Bisset L et al. Mobilisation with movement and exercise, corticosteroid injection, or wait and see for tennis elbow; randomised trial. BMJ. 2006 Nov 4;333(7575):939. [PMID: 17012266]

2. Carpal Tunnel Syndrome

Essentials of Diagnosis

- Pain, burning, and tingling in the distribution of the median nerve.
- Initially, most bothersome during sleep.
- Late weakness or atrophy, especially of the thenar eminence.
- Can be caused by repetitive activities using the wrist.
- Commonly seen during pregnancy and in patients with diabetes mellitus or rheumatoid arthritis.

General Considerations

An entrapment neuropathy, carpal tunnel syndrome is a painful disorder caused by compression of the median nerve between the carpal ligament and other structures within the carpal tunnel. The contents of the tunnel can be compressed by synovitis of the tendon sheaths or carpal joints, recent or malhealed fractures, tumors, tissue infiltration, and occasionally congenital syndromes (eg, mucopolysaccharidoses). Even though no anatomic lesion is apparent, flattening or even circumferential constriction of the median nerve may be observed during operative section of the overlying carpal ligament. The disorder may occur in fluid retention of pregnancy, in individuals with a history of repetitive use of the hands, or following injuries of the wrists. There is a familial type of carpal tunnel syndrome in which no etiologic factor can be identified. Carpal tunnel syndrome can also be a feature of many systemic diseases, such as rheumatoid arthritis and other rheumatic disorders (inflammatory tenosynovitis), myxedema, amyloidosis, sarcoidosis, leukemia, acromegaly, and hyperparathyroidism.

Clinical Findings

A. Symptoms and Signs

The initial symptoms are pain, burning, and tingling in the distribution of the median nerve (the palmar surfaces of the thumb, the index and long fingers, and the radial half of the ring finger). Aching pain may radiate proximally into the forearm and occasionally proximally to the shoulder and over the neck and chest. Pain is exacerbated by manual activity, particularly by extremes of volar flexion or dorsiflexion of the wrist. It is most bothersome at night. Impairment of sensation in the median nerve distribution may or may not be demonstrable. Subtle disparity between the affected and opposite sides can be shown by testing for two-point discrimination or by requiring the patient to identify different textures of cloth by rubbing them between the tips of the thumb and the index finger. A Tinel sign may be positive. A Phalen sign is tingling or shock-like pain on volar wrist percussion (Table 41–4). The Phalen sign is pain or paresthesia in the distribution of the median nerve. The Phalen test is performed by gently pressing the volar surface of the wrist against the examiner’s hand while the patient extends the wrist. Reproduction of pain or paresthesia is considered positive. The Phalen test is used to confirm the diagnosis of carpal tunnel syndrome.
from compression syndromes of the median nerve in the forearm or arm, and from mononeuritis multiplex. When left-sided, it may be confused with angina pectoris.

**Treatment**

Treatment is directed toward relief of pressure on the median nerve. When a causative lesion is discovered, it should be treated appropriately. Otherwise, patients in whom carpal tunnel syndrome is suspected should modify their hand activities and have the affected wrist splinted in the neutral position for up to 3 months. Oral corticosteroids or NSAIDs can also be tried. Carpal tunnel release surgery can be beneficial if the patient has a positive electrodiagnostic test, at least moderate symptoms, high clinical probability, unsuccessful nonoperative treatment, and symptoms lasting longer than 12 months.

**When to Refer**

- If symptoms persist > 3 months despite conservative treatment, including the use of a wrist splint.
- If thenar muscle (e.g., abductor pollicis brevis) weakness or atrophy develops.

</tbody>
</table>

SEADS, swelling, erythema, atrophy, deformity, and (surgical) scars.

### B. Imaging

Ultrasound can demonstrate flattening of the median nerve beneath the flexor retinaculum. Sensitivity of ultrasound for carpal tunnel syndrome is variable but estimated between 54% and 98%.

### C. Special Tests

Electromyography and nerve conduction studies show evidence of sensory conduction delay before motor delay, which can occur in severe cases. This syndrome should be differentiated from other cervicobrachial pain syndromes, median nerve when the patient flexes both wrists to 90 degrees for 60 seconds (Table 41–4). The carpal compression test, in which numbness and tingling are induced by the direct application of pressure over the carpal tunnel, may be more sensitive and specific than the Tinel and Phalen tests (Table 41–4). Muscle weakness or atrophy, especially of the thenar eminence, can appear later than sensory disturbances as compression of the nerve worsens.

### 1. Hip Fractures

**Internal rotation of the hip is the best provocative diagnostic maneuver.**

**Hip fractures should be surgically repaired as soon as possible (within 24 hours).**

**Delayed treatment of hip fractures in the elderly leads to increased complications and mortality.**

**General Considerations**

Approximately 4% of the 7.9 million fractures that occur each year in the United States are hip fractures. There is a high mortality rate among elderly patients following hip fracture, with death occurring in 8–9% within 30 days and in approximately 25–30% within 1 year. Osteoporosis, female sex, height > 5-foot 8-inches, and age over 50 years are risk factors for hip fracture. Hip fractures usually occur after a fall. High velocity trauma is needed in younger patients. Stress fractures can occur in athletes or individuals with...
poor bone mineral density following repetitive loading activities.

**Clinical Findings**

**A. Symptoms and Signs**

Patients typically report pain in the groin, though pain radiating to the lateral hip, buttock, or knee can also commonly occur. If a displaced fracture is present, the patient will not be able to bear weight and the leg may be externally rotated. Gentle logrolling of the leg with the patient supine helps rule out a fracture. Examination of the hip demonstrates pain with deep palpation in the area of the femoral triangle (similar to palpating the femoral artery). Provided the patient can tolerate it, the clinician can, with the patient supine, flex the hip to 90 degrees with the knee flexed to 90 degrees. The leg can then be internally and externally rotated to assess the range of motion on both sides. Pain with internal rotation of the hip is the most sensitive test to identify intra-articular hip pathology. Hip flexion, extension, abduction, and adduction strength can be tested.

Patients with hip stress fractures have less pain on physical examination than described previously but typically have pain with weight bearing. The Trendelenburg test can be performed to examine for weakness or instability of the hip abductors, primarily the gluteus medius muscle (Table 41–5). Another functional test is asking the patient to hop or jump during the examination. If the patient has a compatible clinical history of pain and is unable or unwilling to hop, then a stress fracture should be ruled out. The back should be carefully examined in patients with hip complaints, including examining for signs for sciatica.

Following displaced hip fractures, a thorough medical evaluation and treatment should be pursued to maximize the patients’ ability to undergo operative intervention. Patients who are unable to get up by themselves may have been immobile for hours or even days following their falls. Thus, clinicians must exclude rhabdomyolysis, hyperthermia, deep venous thrombosis, pulmonary embolism, and other conditions that can occur with prolonged immobilization. Delay of operative intervention leads to an increased risk of perioperative morbidity and mortality.

**B. Imaging**

Useful radiographic views of the hip include anteroposterior views of the pelvis and bilateral hips and frog-leg lateral views of the painful hip. A CT scan or MRI may be necessary to identify the hip fracture pattern or to evaluate non-displaced fractures. Hip fractures are generally described by location, including femoral neck, intertrochanteric, or subtrochanteric.

**C. Treatment**

Almost all patients with a hip fracture will require surgery and may need to be admitted to hospital for pain control while they await surgery. Surgery is recommended within the first 24 hours because studies have shown that delaying surgery 48 hours results in at least twice the rate of major and minor medical complications, including pneumonia, decubitus ulcers, and deep venous thrombosis.

Stress fractures in active patients require a period of protected weight-bearing and a gradual return to activities, although it may take 4–6 months before a return to normal activities. Femoral neck fractures are commonly treated with hemiarthroplasty or total hip replacement. This allows the patient to begin weight-bearing immediately postoperatively. Peritrochanteric hip fractures are treated with open reduction internal fixation, where plate and screw construct or intramedullary devices are used. The choice of implant will depend on the fracture pattern. Since fracture fixation requires the fracture to proceed to union, the patient may need to have protected weight-bearing during the early postoperative period. Dislocation, periprosthetic fracture, and avascular necrosis of the hip are common complications after surgery.

Patients should be mobilized as soon as possible postoperatively to avoid pulmonary complications and decubitus ulcers. Supervised physical therapy and rehabilitation is important for the patient to regain as much function as possible. Unfortunately, most patients following hip fractures will lose some degree of independence.

**D. Prevention**

Bone density screening can identify patients at risk for osteopenia or osteoporosis, and treatment can be planned accordingly. Nutrition (calcium and vitamin D intake) and bone health (bone densitometry, serum calcium and 25-OH vitamin D levels) should be reviewed with the

patient (see Chapter 26). For patients with decreased mobility, systemic anticoagulation with low-molecular-weight heparin or warfarin should be considered to avoid deep venous thrombosis (see Table 14–13). Fall prevention exercise programs are available for elderly patients at risk for falls and hip fractures. Hip protectors are uncomfortable and have less use in preventing fractures.

When to Refer

All patients in whom hip fracture is suspected.

2. Osteoarthritis

Essentials of Diagnosis

- Pain deep in the groin on the affected side.
- Swelling.
- Degeneration of joint cartilage.
- Loss of active and passive range of motion in severe osteoarthritis.

General Considerations

In the United States, the prevalence of osteoarthritis will grow as the number of persons over age 65 years doubles to more than 70 million by 2030. Cartilage loss and osteoarthritis symptoms are preceded by damage to the collagen-proteoglycan matrix. The etiology of osteoarthritis is often multifactorial, including previous trauma, prior high-impact activities, genetic factors, obesity, and rheumatologic or metabolic conditions.

Clinical Findings

A. Symptoms and Signs

Osteoarthritis usually causes pain in the affected joint with loading of the joint or at the extremes of motion. Mechanical symptoms—such as swelling, grinding, catching, and locking—suggest internal derangement, which is indicated by damaged cartilage or bone fragments that affect the smooth range of motion expected at an articular joint. Pain can also produce the sensation of “buckling” or “giving way” due to muscle inhibition. As the joint degeneration becomes more advanced, the patient loses active range of motion and may lose passive range of motion as well.

Patients complain of pain deep in the groin on the affected side and have problems with weight-bearing activities such as walking, climbing stairs, and getting up from a chair. They may limp and develop a lurch during their gait, leaning toward the affected side as the walk to reduce pressure on the hip.

B. Imaging

Weight-bearing radiographs of the affected hip are preferred for evaluation of hip osteoarthritis. To reduce radiation exposure, obtain an anteroposterior weight-bearing radiograph of the pelvis with a lateral view of the symptomatic hip. Joint space narrowing and sclerosis suggest early osteoarthritis, while osteophytes near the femoral head or acetabulum and subchondral bone cysts are more advanced changes.

Treatment

A. Conservative

Changes in the articular cartilage are irreversible. Therefore, a cure for the diseased joint is not possible, although symptoms or structural issues can be addressed to try to maintain activity level. Conservative treatment for patients with osteoarthritis includes activity modification, therapeutic exercises, weight loss, and use of assistive devices (such as a cane). Lifestyle modifications also include proper footwear and avoidance of high impact activities.

Analgesics may be effective in some cases. Corticosteroid injections can be considered for short-term relief of pain; however, hip injections are best performed under fluoroscopic, ultrasound, or CT guidance to ensure accurate injection in the joint. Use of viscosupplementation in the hip has been studied with modest improvements; however, it remains an off-label use at this time.

B. Surgical

Two published randomized trials demonstrate that arthroscopy does not improve outcomes at 1 year over placebo or routine conservative treatment of osteoarthritis. Arthroscopic surgery is indicated in patients with osteoarthritis if, rather than pain, they have mechanical symptoms and internal derangement symptoms that can be removed as the main complaint. Such surgical treatments are useful to restore range of motion by removing osteophytes, cartilage fragments, or loose bodies.

Joint replacement surgeries are effective and cost-effective for patients with significant symptoms and functional limitations, providing improvements in pain, function, and quality of life. Minimally invasive surgeries and computer-assisted navigation during operation are being investigated as methods to improve techniques (eg, accurate placement of the hardware implant) and to reduce complication rates.

Hip resurfacing surgery is a newer joint replacement technique. Rather than use a traditional artificial joint implant of the whole neck and femur, only the femoral head is removed and replaced. Concerns following resurfacing surgery include the risk of femoral neck fracture and collapse of the head. The cumulative survival rate of this implant at 10 years from recent studies is estimated to be 94%. Evidence so far suggests that hip resurfacing is...
comparable to total hip replacement and is a viable alternative for younger patients.

When to Refer

Patients with sufficient disability, limited benefit from conservative therapy, and evidence of severe osteoarthritis can be referred for joint replacement surgery.

Clinical Findings

A. Symptoms and Signs

Evaluation of knee pain should begin with general questions regarding duration and rapidity of symptom onset and the mechanism of injury or aggravating symptoms. Overuse or degenerative problems can occur with stress or compression from sports, hobbies, or occupation. A history of trauma, previous orthopedic problems with, or surgery to, the affected knee should also be specifically queried. Symptoms of infection (fever, recent bacterial infections, risk factors for sexually transmitted infections [such as gonorrhea] or other bacterial infections [such as staphylococcal infection]) should always be elicited.

Common symptom complaints include the following:

1. Presence of grinding, clicking, or popping with bending, may be indicative of osteoarthritis or the patellofemoral syndrome.
2. “Locking” or “catching” when walking suggests an internal derangement, such as meniscal injury or a loose body in the knee.
3. Intra-articular swelling of the knee or an effusion indicates an internal derangement or a synovial pathology. Large swelling may cause a popliteal (Baker) cyst. Acute swelling within minutes to hours suggests a hemarthrosis, most likely due to an ACL injury, fracture or patellar dislocation, especially if trauma is involved.
4. Lateral “snapping” with flexion and extension of the knee may indicate inflammation of the iliotibial band.
5. Pain that is worsened with bending and walking downstairs suggests issues with the patellofemoral joint, usually degenerative such as chondromalacia of the patella or osteoarthritis.
6. Pain that occurs when rising after prolonged sitting suggests a problem with tracking of the patella.

A careful history, coupled with a physical examination that includes observation, palpation and range of motion testing, as well as specific tests for particular anatomic structures is frequently sufficient to establish a diagnosis. When there is a knee joint effusion caused by increased fluid in the intra-articular space, physical examination will demonstrate swelling in the hollow or dimple around the patella and distention of the suprapatellar space.

Table 41–6 shows the differential diagnosis of knee pain, and Table 41–7 outlines possible diagnoses based on the location of pain.
An injury involving an audible pop when the knee buckles.
- Acute swelling immediately (or within 4 hours).
- Instability occurs with lateral movement activities and going down stairs.

### General Considerations

The anterior cruciate ligament (ACL) connects the posterior aspect of the lateral femoral condyle to the anterior aspect of the tibia. Its main function is to control anterior translation of the tibia on the femur. It also provides rotationally stability of the tibia on the femur. ACL tears are common with sporting injuries. They can result from both contact (valgus blow to the knee) and non-contact (jumping, pivoting, and deceleration) activities. The patient usually falls down following the injury, has acute swelling and difficulty with weight-bearing, and complains of instability. ACL injuries are common in skiing, soccer, football, and basketball among young adolescents and middle-age patients. Pre-pubertal and older patients usually sustain fractures instead of ligamentous injuries.

### Clinical Findings

#### A. Symptoms and Signs

Acute ACL injuries usually lead to acute swelling of the knee, causing difficulty with motion. After the swelling has resolved, the patient can walk with a "stiff-knee" gait or quadriiceps avoidance gait because of the instability. More importantly, patients describe symptoms of instability while performing side-to-side maneuvers or descending stairs. Stability tests assess the amount of laxity of the knee while performing side-to-side maneuvers or descending stairs. The Lachman test (84–87% sensitivity and 93% specificity) is performed with the patient lying supine and the knee flexed to 20–30 degrees (Table 41–8). The clinician grasps the distal femur from the lateral side and the proximal tibia with the other hand on the medial side. With the knee in neutral position, stabilize the femur, and pull the tibia anteriorly using a similar force to lifting a 10-to 15-pound weight. Excessive anterior translation of the tibia compared with the other side indicates injury to the ACL. The anterior drawer test (48% sensitivity and 87% specificity) is performed with the patient lying supine and the knee flexed to 90 degrees (Table 41–8). The clinician

<table>
<thead>
<tr>
<th>Maneuver</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pivot shift</td>
<td>Used to determine the amount of rotational laxity of the knee. The patient is examined while lying supine with the knee in full extension. It is then slowly flexed while applying internal rotation and a valgus stress. The clinician feels for a subluxation at 20–40 degrees of knee flexion. The patient must remain very relaxed to have a positive test.</td>
</tr>
</tbody>
</table>

Valgus stress

Performed with the patient supine. The clinician should stand on the outside of the patient’s knee. With one hand, the clinician should hold the ankle while the other hand is supporting the leg at the level of the knee joint. A valgus stress is applied at the ankle to determine pain and laxity of the medial collateral ligament. The test should be performed at both 30 degrees and at 0 degrees of knee extension.
Varus stress

The patient is again placed supine. For the right knee, the clinician should be standing on the right side of the patient. The left hand of the examiner should be holding the ankle while the right hand is supporting the lateral thigh. A varus stress is applied at the ankle to determine pain and laxity of the lateral collateral ligament. The test should be performed at both 30 degrees and at 0 degrees of knee flexion.

The sag sign

The patient is placed supine and both hips and knees are flexed up to 90 degrees. Because of gravity, the posterior cruciate ligament-injured knee will have an obvious set-off at the anterior tibia which is “sagging” posteriorly.

Posterior drawer

The patient is placed supine with the knee flexed at 90 degrees (see Anterior drawer figure above). In a normal knee, the anterior tibia should be positioned about 10 mm anterior to the femoral condyle. The clinician can grasp the proximal tibia with both hands and push the tibia posteriorly. The movement, indicating laxity and possible tear of the posterior cruciate ligament, is compared with the uninjured knee.

Meniscal signs

McMurray test

Performed with the patient lying in supine. The clinician flexes the knee until the patient reports pain. For this test to be valid, it must be flexed pain-free beyond 90 degrees. The clinician externally rotates the patient’s foot and then extends the knee while palpating the medial knee for “click” in the medial compartment of the knee or pain reproducing pain from a meniscus injury. To test the lateral meniscus, the same maneuver is repeated while rotating the foot internally (53% sensitivity and 59–97% specificity).
Table 41–8. Knee examination. (continued)

| Maneuver              | Description                                                                                                                                 |

| Modified McMurray     | Performed with the hip flexed to 90 degrees. The knee is then flexed maximally with internally or externally rotation of the lower leg. The knee can then be rotated with the lower leg in internal or external rotation to capture the torn meniscus underneath the condyles. A positive test is pain over the joint line while the knee is being flexed and internally or externally rotated. |
| Thessaly test         | Performed with the patient standing on one leg with knee slightly flexed. The patient is asked to twist the knee while standing on one leg. Pain can be elicited during twisting motion. |
| Patellofemoral joint test | Apprehension sign Suggests instability of the patellofemoral joint and is positive when the patient becomes apprehensive when the patella is deviated laterally. |

SEADS, swelling, erythema, atrophy, deformity, and (surgical) scars.
stabilizes the patient’s foot by sitting on it and grasps the proximal tibia with both hands around the calf and pulls anteriorly. A positive test finds ACL laxity compared with the unaffected side. The pivot shift test is used to determine the amount of rotational laxity of the knee (Table 41–8). The patient is examined while lying supine with the knee in full extension. It is then slowly flexed while applying internal rotation and a valgus stress. The clinician feels for a subluxation at 20–40 degrees of knee flexion. The patient must remain very relaxed to have a positive test.

### B. Imaging

Plain radiographs are usually negative in ACL tears but are useful to rule out fractures. A small avulsion injury can sometimes be seen over the lateral compartment of the knee. This is called a “segond” fracture and is pathognomonic of an ACL injury. MRI is the best method to diagnose ACL tears. It has > 95% sensitivity and specificity for ACL tears. MRI also allows evaluation of other associated structures, such as menisci and cartilages.

### Treatment

Most young and active patients will require surgical reconstruction of the ACL. Common surgical techniques use the patient’s own tissues, usually the patellar or hamstring tendons (autograft) or a cadaver graft (allograft) to arthroscopically reconstruct the torn ACL. Different patients groups experienced improved results with specific surgical graft choices. Recovery from surgery usually requires 6 months. Nonoperative treatments are usually reserved for older patients or those with a very sedentary lifestyle. Physical therapy can focus on hamstring strengthening and core stability. An ACL brace can help stability. Longitudinal studies have demonstrated that nonoperative management of an ACL tear can lead to a higher incidence of meniscus tears.

### When to Refer

- Almost all ACL tears should be referred to an orthopedic surgeon for evaluation.
- Individuals with instability in the setting of a chronic ACL tear (> 6 months) should be considered for surgical reconstruction.
- Patients with an ACL tear and associated meniscus or articular injuries may benefit from surgery to address the other injuries.

### 3. Collateral Ligament Injury

#### ESSENTIALS OF DIAGNOSIS

- Caused by a valgus or varus blow or stress to the knee.
- Pain and instability in the affected area.
- Limited range of motion.

#### General Considerations

The medial collateral ligament (MCL) is the most commonly injured ligament in the knee. It is usually injured with a valgus stress to the partially flexed knee. It can also occur with a blow to the lateral leg. The MCL is commonly injured with acute ACL injuries. The lateral collateral ligament (LCL) is less commonly injured, but this can occur with a medial blow to the knee. Since both collateral ligaments are extra-articular, injuries to these ligaments may not lead to any intra-articular effusion. Affected patients may have difficulty walking initially, but this can improve when the swelling decreases.

#### Clinical Findings

##### A. Symptoms and Signs

The main clinical findings for patients with collateral ligament injuries are pain along the course of the ligaments. The patient may have limited range of motion due to pain, especially during the first 2 weeks following the injury. The best tests to assess the collateral ligaments are the varus and valgus stress tests. The sensitivity of the tests is as high as 86–96%.

The varus stress test is performed with the patient supine (Table 41–8). The clinician should stand on the outside of the patient’s knee. With one hand, the clinician should hold the ankle while the other hand is supporting the leg at the level of the knee joint. A valgus stress is applied at the ankle to determine pain and laxity of the MCL. The test should be performed at both 30 degrees and at 0 degrees of knee extension.

For the valgus stress test, the patient is again placed supine (Table 41–8). For the right knee, the clinician should be standing on the right side of the patient. The clinician’s left hand should be holding the ankle while the right hand is supporting the lateral thigh. A varus stress is applied at the ankle to determine pain and laxity of the LCL. The test should be performed at both 30 degrees and at 0 degrees of knee flexion.

The test results can be graded from 1–3. Grade 1 is when the patient has pain with varus/valgus stress test but no instability. With grade 2 injuries, the patient has pain, and the knee shows instability at 30 degrees of knee flexion. In grade 3 injuries, the patient has marked instability but not much pain. The knee is often unstable at both 30 degrees and 0 degrees of knee flexion.
B. Imaging

Radiographs are usually nondiagnostic except for avulsion injuries. However, radiographs should be used to rule out fractures that can occur with collateral ligament injuries. Isolated MCL injuries usually do not require evaluation by MRI, but MRI should be used to evaluate possible associated cruciate ligament injuries. LCL or posterolateral corner injuries should have MRI evaluation to exclude associated injuries and to determine their significance.

Treatment

The majority of MCL injuries can be treated with protected weight-bearing and physical therapy. For grade 1 and 2 injuries, the patient can usually bear weight as tolerated with full range of motion. A hinged knee brace can be given to patients with grade 2 MCL tears to provide stability. Early physical therapy is recommended to protect range of motion and muscle strength. Grade 3 MCL injuries require long leg braces to provide stability. Patients can weight-bear but only with the knee locked in extension with a brace. The motion can then be increased with the brace unlocked. Grade 3 injuries can take up to 6–8 weeks to heal. MCL injuries rarely need surgery. LCL injuries usually require surgical repair or reconstruction.

When to Refer

- Symptomatic instability with chronic MCL tears or acute MCL tears with other ligamentous injuries.
- LCL or posterolateral corner injuries require urgent surgical repair or reconstruction (within 1 week).

4. Posterior Cruciate Ligament Injury

The posterior cruciate ligament (PCL) is the strongest ligament in the knee. PCL injuries usually represent significant trauma and are highly associated with multi-ligament injuries and knee dislocations. More than 70–90% of PCL injuries have associated injuries to the posterolateral corner, MCL, and ACL. There should be high suspicion for neurovascular injuries and a thorough neurovascular examination of the limb should be performed.

Clinical Findings

A. Symptoms and Signs

Most patients with acute injuries have difficulty with ambulation. Patients with chronic PCL injuries can ambulate without gross instability but may complain of subjective “looseness” and often report pain and dysfunction, especially with bending. Clinical examinations of PCL injuries include the “sag sign” (Table 41–8). The patient is placed supine and both hips and knees are flexed up to 90 degrees. Because of gravity, the PCL-injured knee will have an obvious set-off at the anterior tibia which is “sagging” posteriorly. The PCL ligament can also be examined using the posterior drawer test (90% sensitivity and 99% specificity) (Table 41–8). The patient is placed supine with the knee flexed at 90 degrees. In a normal knee, the anterior tibia should be positioned about 10 mm anterior to the femoral condyle. The clinician can grasp the proximal tibia with both hands and push the tibia posteriorly. The movement, indicating laxity and possible tear of the PCL, is compared with the uninjured knee. A PCL injury is sometimes mistaken for an ACL injury during the anterior drawer test since the tibia is subluxed posteriorly in a sagged position and can be abnormally translated forward, yielding a false-positive test for an ACL injury. Pain, swelling, pallor, and numbness in the affected extremity may suggest a knee dislocation with possible injury to the popliteal artery.

B. Imaging

Radiographs are often nondiagnostic but are required to diagnose any fractures. MRI is used to diagnose PCL and other associated injuries.

Treatment

Isolated PCL injuries can be treated nonoperatively. Acute injuries are usually immobilized using a knee brace with the knee extension; the patient uses crutches for ambulation. Physical therapy can help achieve increased range of motion and improved ambulation. Many PCL injuries are associated with other injuries and may require operative reconstruction. Neurovascular injuries occur in up to one-third of all knee dislocations or PCL injuries.

When to Refer

- The patient should be seen urgently within 1–2 weeks.
- If the lateral knee is also unstable with varus stress testing, the patient should be assessed for a posterolateral corner injury, which may require an urgent surgical reconstruction.
- Isolated PCL tears may require surgery if the tear is complete (grade 3) and the patient is symptomatic.
5. Meniscus Injuries

**ESSENTIALS OF DIAGNOSIS**
- Patient may or may not report an injury.
- Joint line pain and pain with deep squatting are the most sensitive signs.
- Difficulty with knee extension suggests an internal derangement that should be evaluated urgently with MRI.

**General Considerations**

The menisci act as shock absorbers within the knee. Injuries to a meniscus can lead to pain, clicking, and locking sensation. Most meniscus injuries occur with acute injuries (usually in younger patients) or repeated microtrauma, such as squatting or twisting (usually in older patients).

**Clinical Findings**

**A. Symptoms and Signs**

The patient may have an antalgic (painful) gait and difficulty with squatting. He or she may complain of catching or locking of the meniscal fragment. Physical findings can include effusion or joint line tenderness. Patients can usually point out the area of maximal tenderness along the joint line. Swelling usually occurs during the first 24 hours after the injury or later. Meniscus tears rarely lead to the immediate swelling that is commonly seen with fractures and ligament tears. Meniscus tears are commonly seen in arthritic knees. However, it is often unclear whether the pain is coming from the meniscus tear or the arthritis.

Provocative tests, including the McMurray test, the modified McMurray test, and the Thessaly test, can be performed to confirm the diagnosis (Table 41–8). Most symptomatic meniscus tears cause pain with deep squatting and when waddling (performing a “duck walk”).

**B. Imaging**

Radiographs are usually normal but may show joint space narrowing, early osteoarthritis changes, or loose bodies. MRI of the knee is the best diagnostic tool for meniscal injuries (93% sensitivity and 95% specificity). High signal through the meniscus (bright on T2 images) represents a meniscal tear.

**Treatment**

Conservative treatment can be used for degenerative tears in older patients. The treatment is similar for patients with mild knee osteoarthritis, including analgesics and physical therapy for strengthening and core stability. Acute tears in young and active patients can be best treated arthroscopically with meniscus repair or debridement. Recent randomized controlled studies have demonstrated no benefit with arthroscopic meniscectomy in patients with advanced osteoarthritis.

**When to Refer**

- If the patient has symptoms of internal derangement suspected as meniscus injury. The patient should receive an MRI to confirm the injury.
- If the patient cannot extend the knee due to a mechanical block, the patient should be evaluated as soon as possible. Certain shaped tears on MRI, such as bucket handle tears, are amenable to meniscal repair surgery.

6. Patellofemoral Pain

**ESSENTIALS OF DIAGNOSIS**
- Pain experienced with bending activities (kneeling, squatting, climbing stairs).
- Lateral deviation or tilting of the patella in relation to the femoral groove.

**General Considerations**

Patellofemoral pain, also known as anterior knee pain or “runner’s knee,” describes any pain involving the patellofemoral joint. The pain affects any or all of the anterior knee structures, including the medial and lateral aspects of the patella as well as the quadriceps and patellar tendon insertions. The patella engages the femoral trochlear groove with approximately 30 degrees of knee flexion. Forces on the patellofemoral joint increase up to three times body weight as the knee flexes to 90 degrees (eg, climbing stairs), and five times body weight when going into full knee flexion (eg, squatting). Abnormal patellar tracking during flexion can lead to abnormal articular cartilage wear and pain. When the patient has ligamentous hyperlaxity, the patella can sublux out of the groove, usually laterally. Patellofemoral pain is also associated with muscle strength and flexibility imbalances as well as altered hip and ankle biomechanics.

**Clinical Findings**

**A. Symptoms and Signs**

Patients usually complain of pain in the anterior knee with bending movements and less commonly in full extension.
Pain from this condition is localized under the kneecap but can sometimes be referred to the posterior knee or over the medial or lateral inferior patella. Symptoms may begin after a trauma or after repetitive physical activity, such as running and jumping. When maltracking, palpable and sometimes audible crepitus can occur.

Intra-articular swelling usually does not occur unless there are articular cartilage defects or if osteoarthritis changes develop. On physical examination, it is important to palpate the articular surfaces of the patella. For example, the clinician can use one hand to move the patella laterally, and use the fingertips of the other hand to palpate the lateral undersurface of patella. Patellar mobility can be assessed by medially and laterally deviating the patella (deviation by one-quarter of the diameter of the kneecap is considered normal; greater than one-half the diameter suggests excessive mobility). The apprehension sign suggests instability of the patellofemoral joint and is positive when the patient becomes apprehensive when the patella is deviated laterally (Table 41–8). The patellar grind test is performed by grasping the knee superior to the patella and pushing it downward with the patient supine and the knee extended, pushing the patella inferiorly. The patient is asked to contract the quadriceps muscle to oppose this downward translation, with reproduction of pain or grinding being the positive sign for chondromalacia of the patella. There are two common presentations: (1) Patients whose ligaments and patella are too loose (hypermobility); (2) and patients who have soft tissues that are too tight leading to excessive pressure on the joint.

Evaluation of the quadriceps strength and hip stabilizers can be accomplished by having the patient perform a one-leg squat without support. Patients who are weak may display poor balance, with dropping of the pelvis (similar to a positive hip Trendelenburg sign) or excessive internal rotation of the knee medially. Normally, with a one-leg squat, the knee should align over the second metatarsal ray of the foot.

B. Imaging

Diagnostic imaging has limited use in younger patients and is more helpful in older patients to assess for osteoarthritis or to evaluate patients who do not respond to conservative treatment. Radiographs may show lateral deviation or tilting of the patella in relation to the femoral groove. MRI may show thinning of the articular cartilage but is not clinically necessary, except prior to surgery or to exclude other pathology.

Treatment

A. Conservative

For symptomatic relief, use of local modalities such as ice and anti-inflammatory medications can be beneficial. If the patient has signs of patellar hypermobility, physical therapy exercises are useful to strengthen the quadriceps (especially the vastus medialis obliquus muscle) to help stabilize the patella and improve tracking. Support for the patellofemoral joint can be provided by use of a patellar stabilizer brace or special taping techniques (McConnell taping). Correcting lower extremity alignment (with appropriate footwear or over-the-counter orthotics) can help improve symptoms, especially if the patient has pronation or high arched feet. If the patient demonstrates tight peripatellar soft tissues, special focus should be put on stretching the hamstrings, iliotibial band, quadriceps, calves and hip flexors. Strengthening exercises should include the quadriceps and hip abductors.

B. Surgical

Surgery is rarely needed and is considered a last resort for patellofemoral pain. Procedures performed include lateral release or patellar realignment surgery.

When to Refer

Patients with persistent symptoms.

7. Osteoarthritis

Essentials of Diagnosis

- Degeneration of joint cartilage.
- Pain with bending or twisting activities.
- Swelling.
- Loss of active and passive range of motion in severe osteoarthritis.

General Considerations

In the United States, the prevalence of osteoarthritis will grow as the number of persons over age 65 years doubles to more than 70 million by 2030. The incidence of knee osteoarthritis in the United States is 240 per 100,000 person-years.

Cartilage loss and osteoarthritis symptoms are preceded by damage to the collagen-proteoglycan matrix. The etiology of osteoarthritis is often multifactorial including previous trauma, prior high-impact activities, genetic factors, obesity, and rheumatologic or metabolic conditions.

Clinical Findings

A. Symptoms and Signs

Osteoarthritis usually causes pain in the affected joint with loading of the joint or at the extremes of motion.
Mechanical symptoms—such as swelling, grinding, catching, and locking—suggest internal derangement, which is indicated by damaged cartilage or bone fragments that affect the smooth range of motion expected at an articular joint. Pain can also produce the sensation of “buckling” or “giving way” due to muscle inhibition. As the joint degeneration becomes more advanced, the patient loses active range of motion and may lose passive range of motion as well.

As the condition worsens, patients with knee osteoarthritis have an increasingly limited ability to walk. Symptoms include pain with bending or twisting activities, and going up and down stairs. Swelling, limping, and pain while sleeping are common complaints with osteoarthritis, especially as it progresses.

B. Imaging
The most commonly recommended radiographs include bilateral weight-bearing 45-degree bent knee posteroanterior, lateral, and patellofemoral joint views (Merchant view). Radiographic findings include diminished width of the articular cartilage causing joint space narrowing, subchondral sclerosis, presence of osteophytes, and cystic changes in the subchondral bone. MRI of the knee is most likely unnecessary unless other pathology is suspected, including ischemic osteonecrosis of the knee.

▶ Treatment

A. Conservative
Changes in the articular cartilage are irreversible. Therefore, a cure for the diseased joint is not possible, although symptoms or structural issues can be addressed to try to maintain activity level. Conservative treatment for all patients with osteoarthritis includes activity modification, therapeutic exercises, and weight loss. Lifestyle modifications also include proper footwear and avoidance of high impact activities.

Use of a cane in the hand opposite to the affected side is mechanically advantageous. Knee sleeves or braces provide some improvement in subjective pain symptoms most likely due to improvements in neuromuscular function. If patients have unicompartamental osteoarthritis in the medial or lateral compartment, joint unloader braces are available to offload the degenerative compartment. Cushioning footwear and appropriate orthotics or shoe adjustments are useful for reducing impact to the lower extremities.

The initial drugs of choice for the treatment of pain in knee osteoarthritis are oral acetaminophen and topical capsaicin. If a traditional NSAID is indicated, the choice should be based on cost, side-effect profile, and compliance. The cyclooxygenase (COX)-2 inhibitor, celecoxib, is no more effective than traditional NSAIDs; it may offer short-term, but probably not long-term, advantage in preventing gastrointestinal complications. Due to its cost and potential cardiovascular risk, celecoxib should be reserved for carefully selected patients. The role of topical NSAIDs are being considered in the osteoarthritis treatment algorithm, as they do avoid many of the traditional NSAID complications. Opioids can be used appropriately in patients with severe osteoarthritis (see Chapter 5). Glucosamine and chondroitin sulfate are supplements that have been widely used and marketed for osteoarthritis. Evidence for their effectiveness in slowing or reversing cartilage loss is limited and any effect present appears to be small. Despite some initial promise, the best-controlled studies indicate these supplements are ineffective as analgesics in osteoarthritis. However, they have minimal side effects and may be appropriate if the patient experiences subjective benefit.

Knee joint corticosteroid injections are options to help reduce pain and inflammation and can provide short-term pain relief, usually lasting about 6–12 weeks. Viscosupplementation by injections of hyaluronic acid-based products improves synovial fluid viscosity by increasing the molecular weight and quantity of hyaluronic acid beyond that naturally synthesized by the synovium. Laboratory studies also demonstrate that hyaluronic acid injections decrease inflammatory cytokines and free radicals. A review of five meta-analysis studies of viscosupplementation demonstrates a modest benefit. Studies also demonstrate more prolonged effects of viscosupplementation products compared with corticosteroid injection with symptom improvement for > 6 months in some patients with mild knee osteoarthritis.

B. Surgical
Two published randomized trials demonstrate that arthroscopy does not improve outcomes at 1 year over placebo or routine conservative treatment of osteoarthritis. Arthroscopic surgery is indicated in patients with osteoarthritis if, rather than pain, they have mechanical symptoms and internal derangement symptoms. Such surgical treatments are useful to restore range of motion by removing osteophytes, cartilage fragments, or loose bodies.

Joint replacement surgeries are effective and cost-effective for patients with significant symptoms or functional limitations, providing improvements in pain, function, and quality of life. Minimally invasive surgeries and computer-assisted navigation during operation are being investigated as methods to improve techniques (eg, accurate placement of the hardware implant) and to reduce complication rates.

Knee realignment surgery, such as high tibial osteotomy or partial knee replacement surgery, is indicated in patients younger than age 60 with unicompartmental osteoarthritis, who would benefit from delaying total knee replacement. Knee joint replacement surgery has been very successful in improving outcomes for patient with end-stage osteoarthritis. Recent long-term series describe > 95% survival rate of the implant at 15 years.

▶ When to Refer
Patients with sufficient disability, limited benefit from conservative therapy, and evidence of severe osteoarthritis can be referred for joint replacement surgery.
B. Imaging

Routine ankle radiographic views include the anteroposterior, lateral, and oblique (mortise) views. Less common views requested include the calcaneal view and subtalar view. Ottawa Ankle Rules are clinical prediction rules to guide the need for radiographs and have a 97% sensitivity and 99% negative predictive value. If the patient is unable to bear weight immediately in the office setting or emergency department for four steps, then the clinician should check for (1) bony tenderness at the posterior edge of the medial or lateral malleolus and (2) bony tenderness over the navicular (medial midfoot) or at the base of the fifth metatarsal. If either malleoli demonstrates pain or deformity, then ankle radiographs should be obtained. If the foot has bony tenderness, obtain foot radiographs. An MRI is helpful when considering the associated injuries.

Ankle sprains are the most common sports injuries seen in outpatient clinics. Patients usually report “turning the ankle” during a fall or after landing on an irregular surface such as a hole or an opponent’s foot. The most common mechanism of injury is an inversion and plantarflexion sprain, which injures the anterior talofibular ligament (ATF) ligament rather than the calcaneofibular ligament (CF) ligament. Other injuries that can occur with inversion ankle injuries are listed in (Table 41–9).

**General Considerations**

Ankle sprains are the most common sports injuries seen in outpatient clinics. Patients usually report “turning the ankle” during a fall or after landing on an irregular surface such as a hole or an opponent’s foot. The most common mechanism of injury is an inversion and plantarflexion sprain, which injures the anterior talofibular ligament (ATF) ligament rather than the calcaneofibular ligament (CF) ligament. Other injuries that can occur with inversion ankle injuries are listed in (Table 41–9).

**Clinical Findings**

**A. Symptoms and Signs**

The usual symptoms following a sprain include localized pain and swelling over the lateral aspect of the ankle, difficulty weight bearing, and limping. The patient’s ankle may feel unstable. On examination, there may be swelling or bruising over the lateral aspect of the ankle. The anterior, inferior aspect below the lateral malleolus is most often the point of maximal tenderness consistent with ATF and CF ligament injuries. The swelling may limit motion of the ankle. Special stress tests for the ankle include the anterior drawer test (Table 41–10) and subtalar tilt test (Table 41–10). In order to grade the severity of ankle sprains, no laxity on stress tests is considered a grade 1 injury, laxity of the ATF ligament on anterior drawer testing but a negative tilt test is a grade 2 injury, and both positive drawer and tilt tests signify a grade 3 injury.

**B. Imaging**

Routine ankle radiographic views include the anteroposterior, lateral, and oblique (mortise) views. Less common views requested include the calcaneal view and subtalar view. Ottawa Ankle Rules are clinical prediction rules to guide the need for radiographs and have a 97% sensitivity and 99% negative predictive value. If the patient is unable to bear weight immediately in the office setting or emergency department for four steps, then the clinician should check for (1) bony tenderness at the posterior edge of the medial or lateral malleolus and (2) bony tenderness over the navicular (medial midfoot) or at the base of the fifth metatarsal. If either malleoli demonstrates pain or deformity, then ankle radiographs should be obtained. If the foot has bony tenderness, obtain foot radiographs. An MRI is helpful when considering the associated injuries.

**Treatment**

Immediate treatment of an ankle sprain follows the MICE mnemonic: modified activities, ice, compression, and elevation. Subsequent treatment involves protected weight bearing with crutches and use of an ankle stabilizer brace, especially for grade 2 and 3 injuries. Early motion is essential, and patients should be encouraged to do home exercises or physical therapy. Proprioception and balance exercises (eg, “wobble board”) are useful to restore function to the ankle and prevent future ankle sprains. Regular use of an ankle support with activities can reduce the risk of lateral ankle sprains. Chronic instability can develop after acute ankle sprain in 10–20% of people and may require surgical stabilization with ligament reconstruction surgery.

**When to Refer**

- Ankle fractures.
- Recurrent ankle sprains or signs of chronic ligamentous ankle instability.
Clinical Findings

A. Symptoms and Signs

Symptoms of a high ankle sprain include severe and prolonged pain over the anterior ankle at the anterior tibiofibular ligament, worse with weight bearing. This is often more painful than the typical ankle sprain. The point of maximal tenderness involves the anterior tibiofibular ligament, which is higher than the ATF ligament. It is also important to palpate the proximal fibula to rule out any proximal syndesmotic ligament injury and associated fracture known as a “maisonneuve fracture.” There is often some mild swelling in this area, and the patient may or may not have an ankle effusion. The patient usually has limited range of motion in all directions. The external rotation stress test reproduces the mechanism of injury (Table 41–10). (Note: The patient’s foot should have an intact neurovascular examination before undertaking this test.)

B. Imaging

Radiographs of the ankle should include the anteroposterior, mortise, and lateral views. The mortise view may demonstrate loss of the normal overlap between the tibia and fibula, which should be at least 1–2 mm. Asymmetry in the joint space around the tibiotalar joint suggests disruption of the syndesmotic ligaments. If there is proximal tenderness in the lower leg especially around the fibula, an anteroposterior and lateral view of the tibia and fibula should be obtained to rule out a proximal fibula fracture. MRI is the best method to visualize injury to the tibiofibular ligament and to assess status of the other ligaments and the articular cartilage.

2. Eversion (“High”) Ankle Sprains

- Severe and prolonged pain.
- Limited range of motion.
- Mild swelling.
- Difficulty with weight bearing.

General Considerations

A syndesmotic injury or “high ankle” sprain involves the anterior tibiofibular ligament in the anterolateral aspect of the ankle, superior to the anterior talar (ATF) ligament. The injury mechanism often involves the foot being turned out or externally rotated and everted (eg, when being tackled). This injury is commonly missed or misdiagnosed as an ATF ligament sprain on initial visit.

</tbody>
</table>

SEADS, swelling, erythema, atrophy, deformity, and (surgical) scars.
**Treatment**

Whereas most ankle sprains are treated with early motion and weight bearing, treatment for a high ankle sprain should be conservative with a cast or walking boot for 4–6 weeks. Thereafter, protected weight bearing with crutches is recommended until the patient can walk pain-free. Physical therapy can start early to regain range of motion and maintain strength with limited weight-bearing initially.

**When to Refer**

If there is widening of the joint space and asymmetry at the tibiotalar joint, the patient should be referred urgently to a foot and ankle surgeon. Severe or prolonged persistent cases that do not heal may require internal fixation to avoid chronic instability at the tibiofibular joint.

The field of women’s health encompasses more than the reproductive health issues commonly addressed by obstetricians and gynecologists; it evaluates diseases and conditions only seen or experienced in women or experienced by women in ways different than men, as well as the evidence-based prevention and treatment of risk factors and diseases in women. Hence, all primary care providers, including internists and family physicians, should be well versed in women’s health issues.

**PREVENTIVE HEALTH CARE**

Prevention of disease can be **primary** (preventing disease before it happens as well as identifying and modifying risk factors), **secondary** (identifying early disease), or **tertiary** (treating complications of the disease or limiting the impact of established disease). Important areas for primary prevention include encouraging women to exercise regularly to reduce the risk of coronary heart disease (CHD) and breast cancer as well as counseling women to discontinue smoking to reduce the risk of cardiac and lung diseases. Cancer screening in women focuses on secondary prevention, so that disease is detected early when prompt treatment improves outcome.

**CARDIOVASCULAR DISEASE PREVENTION**

Although cardiovascular disease is the leading cause of death in women, they are often more concerned about developing breast cancer (see below) than about developing heart disease. While some heart disease risk factors such as age and family history are not modifiable, as with men, other risk factors such as hypertension, hyperlipidemia, smoking, obesity, and diabetes are potentially modifiable. The Framingham risk calculator (http://hp2010.nhlbi.nih.gov/atpiii/calculator.asp?usertype=prof) can be used to estimate a woman’s 10-year risk of CHD based on her age, smoking status, blood pressure, and cholesterol levels.

**Modifiable Risk Factors**

**A. Hypertension**

Hypertension is a risk factor for CHD and stroke in both men and women. Approximately 70–80% of women over age 70 have hypertension. A woman with high blood pressure is at lower risk for CHD than a similar aged man. For many young and otherwise healthy women, drug treatment can be deferred, since their absolute risk of CHD in the next 10 years is likely to be low. When pharmacotherapy is started, the choice of medication is similar to those used in men (see Chapter 11).

**B. Hyperlipidemia**

Hyperlipidemia is a CHD risk factor in both men and women, but low levels of high-density lipoprotein (HDL) is more predictive of CHD risk in women. Elevated cholesterol is defined as a total cholesterol > 240 mg/dL (> 7.2 mmol/L) or low-density lipoprotein (LDL) cholesterol > 160 mg/dL (≥ 4.8 mmol/L). Borderline cholesterol is defined as a total cholesterol between 200 mg/dL and 240 mg/dL (6 mmol/L and 7.2 mmol/L) or an LDL cholesterol of 130–159 mg/dL (3.9–4.77 mmol/L). Ideal cholesterol is defined as a total cholesterol < 200 mg/dL (< 6 mmol/L) or an LDL < 130 mg/dL (< 3.9 mmol/L) and an HDL cholesterol > 50 mg/dL (≥ 1.5 mmol/L).

The US Preventive Services Task Force (USPSTF) recommends screening all women aged 45 and older for hyperlipidemia, whereas the National Cholesterol Education Program (NCEP) recommends screening all individuals aged 20 and over. Before screening a woman for hyperlipidemia, an important consideration is whether or not treatment recommendations will change based on the results. Since therapeutic lifestyle changes are recommended for all women, the question is at what point should medication treatment be considered.

There is clear evidence that medication treatment of hyperlipidemia reduces CHD events in women who already have CHD, but when lipid-lowering medications are used...
in women who do not already have CHD, the evidence of benefit is less clear. Decisions about when to initiate medication treatment should include an assessment of an individual’s absolute risk of CHD in the next 10 years. Medication treatment should be targeted toward women with CHD and high-risk women who are most likely to benefit. The NCEP recommends different thresholds at which to initiate medication therapy based on individual CHD risk. For example, for a woman with known CHD, lipid-lowering medication is initiated at an LDL cholesterol of >130 mg/dL, whereas for a woman with 0–1 risk factor, medication therapy is not initiated until the LDL cholesterol measures >190 mg/dL.

C. Diabetes

Diabetes is a CHD risk factor in both men and women. Studies have reached conflicting conclusions about the effect of tight control of diabetes on CHD outcomes in both men and women, although lipid lowering is clearly associated with a reduction in CHD events in diabetic women. All women should focus on primary prevention of diabetes with avoidance of obesity and maintenance of regular exercise.

D. Obesity

Obesity has been established as an independent risk factor for CHD in women. It is not known whether or not weight loss will decrease CHD risk. Since most obese women who lose weight gain it back, the overall goal should be ongoing avoidance of weight gain above normal weight.

E. Predictive Biomarkers and Clinical Tests

The use of high-sensitivity C-reactive protein (hsCRP) has increased in recent years. CRP is an inflammatory biomarker that has been shown to predict cardiovascular events. However, there is currently no evidence that screening for hsCRP improves cardiac outcomes. It has been suggested that measuring hsCRP may be useful in women for whom it would change treatment outcomes, but there is currently no evidence to support this. The USPSTF recently published guidelines outlining the use of nontraditional risk factors in the evaluation of CHD. The risk factors included in the recommendation were hsCRP, ankle-brachial index, leukocyte count, fasting blood glucose, periodontal disease, carotid intima media thickness, coronary artery calcification score, electron beam CT, homocysteine, and lipoprotein (a). The USPSTF concluded that there is insufficient evidence to balance the benefits and harms of screening asymptomatic men and women with no history of CHD to predict CHD events and did not recommend routine screening.

Therapeutic Options for Reducing Risk Factors

A. Aspirin

Aspirin is clearly useful for secondary prevention of CHD in women. Among women who do not have CHD, aspirin reduces the risk of stroke, whereas in men, it reduces the risk of CHD. Before starting an aspirin regimen to reduce the risk of the stroke, women should be assessed for their risk of gastrointestinal bleeding, which is the most common adverse side effect of aspirin use. The USPSTF recommends aspirin in women aged 55–79 years when the potential benefit of a reduction in ischemic strokes outweighs the potential harms of a gastrointestinal hemorrhage. For healthy or at-risk women, 81 mg/d or 100 mg every other day is the suggested dose. For high-risk women, a dose of 75–325 mg/d is recommended.

B. Exercise

Exercise has been associated with a reduction in all causes of cardiovascular mortality. Women often want to know how much exercise is necessary for health benefits. Studies have shown that walking 2.5–3 hours a week is associated with a reduction in cardiovascular disease. The Centers for Disease Control and Prevention and the American College of Sports Medicine recommend that all women accumulate at least 30 minutes a day of moderate intensity physical activity on most if not all days of the week. The Institute of Medicine recommends an hour a day for the goal of maintaining health and ideal body weight.

CANCER PREVENTION

1. Breast Cancer

Risk Factors & Risk Assessment

Breast cancer is the most commonly detected cancer in women and the second leading cause of cancer death. Breast cancer risk is increased with age and with a family history of breast cancer. Women who drink more than two alcoholic drinks per day are at increased risk for breast cancer, and exercise is associated with a decreased risk of breast cancer. Dietary intake has not been conclusively associated with breast cancer risk.

Various models have been used to predict a woman’s risk for breast cancer. The National Cancer Institute has developed the Breast Cancer Risk Assessment Tool, which is based on the Gail Model, and calculates the woman’s risk of developing breast cancer in the next 5 years by considering the following factors: (1) the woman’s age, (2) age at which she had her first menstrual period, (3) age at delivery of first live child, (4) number of first-degree relatives with breast cancer, (4) history of any breast biopsies, and (5) history of atypical hyperplasia. The model has been validated in white women and has been evaluated in black women and found to be relatively accurate, although it may underestimate the risk in black women with a history of previous breast biopsies. It has yet to be validated in women of other ethnicities.

Primary Prevention

In addition to lifestyle modifications, such as exercise and moderation of alcohol intake, chemoprevention of breast cancer is an option for some women. The selective estrogen receptor modifiers (SERMs) tamoxifen and raloxifene have both been shown to reduce invasive breast cancer in high-risk women. However, there are risks associated with SERM treatment. Tamoxifen is associated with an increased risk of endometrial cancer and deep venous thrombosis (DVT). Although raloxifene is not associated with an increased risk of endometrial cancer, the risk of DVT remains. The USPSTF recommends that clinicians discuss chemoprevention with women at high risk for breast cancer and at low risk for the adverse effects of chemoprevention. Clinicians should inform patients of the potential benefits and harms of chemoprevention. Breast cancer risk increases with age, but the risk of adverse effects does as well. Since the clinical trials of tamoxifen and raloxifene for breast cancer prevention used a 1.66% 5-year risk, this risk level is often used as a guide for treatment.

Breast Cancer Screening

Traditional breast cancer screening modalities include screening mammography, clinical breast examination, and breast self-examination. Teaching women to do routine breast self-examination has not been shown to reduce breast cancer mortality. The USPSTF recommends against teaching women to do breast self-examination. The American Cancer Society states that it is acceptable not to do it, but that if women are performing breast self-examination, it is important to ensure that they are doing it correctly. The combination of breast examination done by a clinician and mammography is associated with a decrease in breast cancer mortality, but there is insufficient evidence to recommend clinical breast examination alone.

Mammography reduces breast cancer mortality in women aged 50–74 years and routine mammographic screening is recommended for women in this age group. For women aged 40–49 years, screening has been more controversial. Recent guidelines published by the USPSTF recommend that clinicians not routinely order mammography among 40- to 49-year-old women but rather that they individualize the decision to begin screening, since the number needed to invite to screen to prevent one breast cancer death is much higher in younger women and the number of false-positive and false-negative test results are much higher. Since women over age 75 have not been included in clinical trials and since the likelihood of comorbid diseases limiting life expectancy increases, routine screening of women in this age group is not recommended, but rather the decision making should be individualized.
3. Cervical Cancer

In contrast to most other cancers for which routine screening is recommended, the incidence of cervical cancer is higher in younger women and decreases with age. The major risk factor for cervical cancer is exposure to the human papillomavirus (HPV). Primary prevention of cervical cancer includes avoidance of smoking, postponing sexual debut, and limiting the number of sexual partners. Condom use may also be protective.

➤ Primary Prevention

A quadrivalent HPV vaccine that includes capsid proteins against four HPV types (6, 11, 16, and 18) has been approved for use in girls and women aged 9–26 years to prevent disease associated with these HPV types. A bivalent vaccine (Cervarix) is also available. The published studies, which are based on interim results, show a high degree of efficacy of prevention of vaccine-associated genital warts, persistent infections, and cervical intraepithelial neoplasia. Protection has not been shown against strains that are not in the vaccine or strains that were present before vaccination. The Advisory Committee on Immunization Practices (ACIP) recommends routine vaccination for girls aged 11 or 12 up to age 26, whereas the American Cancer Society recommends the vaccine for girls aged 11–18 but states that there is insufficient evidence to recommend for or against routine vaccination for women aged 19–26. The ACIP also recommends that all 11- and 12-year-old boys get vaccinated against HPV. Unanswered questions about the vaccine include the long-term effects and the length of protection. Receipt of vaccine should not change cervical cancer screening intervals in women.

➤ Secondary Prevention

An important focus of cervical cancer prevention is screening using the Papanicolaou smear. Cervical screening is the biggest success in the history of cancer screening. Cervical cancer mortality has been reduced by about 70% with routine cervical cancer screening. One of the reasons that screening has been so successful is that there is a long preclinical phase where early changes can be detected and treated so as to avoid the development of cancer. In 2012 update, the US Preventive Services Task Force (USPSTF) recommends screening for cervical cancer in women aged 21 to 65 years with cytology (Papanicolaou smear) every 3 years or, for women age 30 to 65 years who want to lengthen the screening interval, screening with a combination of cytology and HPV testing every 5 years. Screening may be done with either liquid-based or conventional cytology. The USPSTF recommends against screening for cervical cancer with HPV testing, alone or in combination with cytology, in women younger than age 30 years. The USPSTF recommends against screening for cervical cancer in women older than age 65 years who have had adequate prior screening and are not otherwise at high risk for cervical cancer. Women with risk factors that place them at higher risk for cervical intraepithelial neoplasia may require more frequent screening. Guidelines from the American College of Obstetricians and Gynecologists (ACOG) state screening should start at age 21 regardless of the onset of sexual activity. ACOG recommends screening every 2 years in women aged 21–29 and every 3 years in women aged 30 and older who have had at least three normal smears. All organizations agree that older women (over age 65 or 70) can stop screening.

Testing for high-risk HPV types is routinely used for the evaluation of abnormal Papanicolaou smears, but their use in routine screening is controversial. Since the prevalence of exposure to high risk HPV types is very high, the potential utility of HPV testing would be finding no evidence of HPV. ACOG and the American Cancer Society recommend co-testing with high risk HPV types as an option, and then rescreening in 3 years if the HPV testing is negative. The USPSTF concludes that the evidence is insufficient to assess the balance of benefits and harms of HPV testing, alone or in combination with cytology for screening for cervical cancer in women aged 30 and older. Given that women with a normal Papanicolaou smear can be rescreened in 3 years, it is not clear what high risk HPV testing for primary screening adds. However, given that the vast majority of cervical cancers occur in women who have never been screened, or who have not been screened in the past 5 years, efforts for cervical cancer prevention should primarily focus on those women.

4. Lung Cancer

Although lung cancer is not typically considered a “woman’s cancer,” it is the leading cause of cancer mortality in both men and women. Primary prevention of lung cancer should be a high priority with encouragement of tobacco cessation among women who smoke. The use of chest radiographs and sputum cytology for cancer screening have not been shown to reduce lung cancer mortality. The National Lung Screening Trial (NLST) compared screening with low-dose CT to screening with chest radiography. High-risk participants (either current or former smokers) received either annual CT or chest radiography for 3 years and were then monitored for 6.5 years. There was a significant reduction in both lung cancer mortality and total mortality with CT screening. However, there were a very large number of false-positive test results, many of which led to additional testing. The USPSTF does not currently recommend any of these modalities for lung cancer screening, although many organizations are in the midst of reassessing their recommendations for lung cancer screening based on the results of the NLST.
5. Ovarian Cancer

Ovarian cancer is a relatively rare but dreaded cancer, with a lifetime incidence of about 1.2% in women with no family history of ovarian cancer. Because it is often detected late, treatment options may be limited.

Many of the risk factors for ovarian cancer such as age and family history are not modifiable, but there are protective factors, including having more than one full-term pregnancy, breast-feeding, and oral contraceptive use. Women at high-risk for ovarian cancer should consider the use of oral contraceptives for as long as it is feasible.

Although screening for ovarian cancer with either the serum marker CA-125 or with transvaginal ultrasound is theoretically appealing, the rarity of the disease limits their use and leads to many false-positive test results. The Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial, where women were screened for ovarian cancer with annual CA-125 and transvaginal ultrasound and monitored for 12.4 years, resulted in no reduction in ovarian cancer mortality. In addition, there were a large number of false-positive test results, some leading to surgical follow-up and resultant surgical complications. The USPSTF does not recommend screening for ovarian cancer.

Osteoporotic fractures are increasing as the population ages. Age and female sex are major risk factors for osteoporotic fractures. Hip and vertebral fractures are associated with premature mortality. Osteoporosis risk can be assessed by measuring bone mineral density (BMD). Normal BMD is no lower than 1.0 standard deviation below the mean for young adult women (t score). Osteopenia is defined as BMD between 1.0 and 2.5 standard deviations below the mean for young adults (t score of –1.0 to –2.5) and osteoporosis is defined as a BMD more than 2.5 standard deviations below the young adult mean (t score < –2.5).

The World Health Organization has developed a fracture risk assessment tool (FRAX, available at http://www.shef.ac.uk/FRAX/index.jsp) that can predict a woman’s 10-year risk of having any osteoporotic fracture and the 10-year risk of hip fracture. Risk factors used in the FRAX tool include age, gender, personal history of fracture, parental history of hip fracture, low body mass index, use of oral corticosteroids, secondary osteoporosis, current smoking, and alcohol intake of three or more drinks per day. It can be used with or without BMD. The FRAX tool is particularly helpful in determining which women with osteopenia are most likely to benefit from treatment. Based on the World Health Organization algorithm adopted for the United States, treatment is recommended when there is a 10-year risk of hip fracture ≥ 3% or a 10-year risk of a major osteoporotic fracture ≥ 20%.

Primary Prevention

Although calcium supplementation is routinely recommended, evidence from the Women’s Health Initiative showed that calcium supplementation did not reduce fracture risk in healthy postmenopausal women. Calcium appears to be necessary but not sufficient for fracture prevention. Recommended calcium intake for women younger than 50 years is 1000 mg/day and for women aged 51 and over, it is 1200 mg/day. Calcium can be given as either calcium citrate or calcium carbonate and should be given with vitamin D. Regular weight bearing exercise has also been associated with an increase in bone density although the effect is lost when the exercise is not continued.

Increasing evidence suggests that vitamin D supplementation is associated with a reduction in fracture risk. Vitamin D can be given as either D$_3$ or D$_2$ formulations. Recommendations are that women aged 70 and younger should consume 600 international units of vitamin D per day, whereas women aged 71 and older should consume 800 international units per day. Individuals with vitamin D deficiency (25-OH vitamin D < 20 mg/mL) may require higher doses, although most recommendations for vitamin D supplementation are based on achieving a serum 25-OH vitamin D concentration of a particular level, rather than on a clinical outcome. Whether or not women should be routinely screened for vitamin D deficiency remains an ongoing question. However, given the association of vitamin D and fractures, checking a 25-OH vitamin D level in women with osteoporosis is reasonable.

Bone Mineral Density Screening

The biggest risk factor for developing osteoporosis is increasing age. Although many women expect to be screened around the time of menopause, routine BMD screening is not recommended until the age of 65. The National Osteoporosis Foundation recommends screening all women age 65 and older and screening younger post-menopausal women if there is a concern based on their risk-factor profile, if they have had a fracture, or if they are discontinuing hormone therapy. The USPSTF recommends screening women aged 65 and older and only screening women aged 60–64 who are at increased risk.

Treatment is generally recommended in women who have a t score < –2.5, who have already had a fracture or who have a t score in the osteopenic range but are at high risk for fracture. Treatment options for osteoporosis are described in Chapter 26.
PREVENTION OF SEXUALLY TRANSMITTED INFECTIONS

Many sexually transmitted infections are asymptomatic in women and some can lead to significant consequences. Primary prevention of sexually transmitted infections includes postponing sexual debut, limiting number of sexual partners, and regular condom use.

The USPSTF and the Centers for Disease Control and Prevention recommend annual screening for Chlamydia trachomatis and gonorrhea in sexually active women age 25 and younger. Screening should continue in women over age 25 and in women who have high-risk sexual behaviors. The Centers for Disease Control and Prevention recommends screening all women for HIV, whereas the USPSTF recommends focusing screening efforts on high-risk individuals. All patients who have a sexually transmitted infection or who seek testing for a sexually transmitted infection should be offered HIV testing.

DEPRESSION SCREENING

Since depression is approximately two times more common in women than in men, clinicians should be alert to symptoms suggesting depression in women. Symptoms include depressed mood, loss of interest in activities, sleep disturbance, change in appetite or weight, psychomotor retardation, difficulty concentrating, feelings of worthlessness, and thoughts of suicide. Low energy or fatigue is a particularly common symptom in women.

There are several clinical surveys for depression screening. The two question screen appears to be effective. Patients are asked “Over the past 2 weeks, have you felt down, depressed or hopeless?” and “Over the past 2 weeks, have you felt little interest or pleasure in doing things?” There is no evidence to suggest that any particular screening tool is superior. A positive screening test should lead to more extensive evaluation.

The USPSTF recommends screening for depression if staff-assisted depression care supports are in place to ensure accurate diagnosis, effective treatment, and follow-up. If these supports are not in place, screening is not recommended.

IMMUNE SYSTEM DISORDERS

There is no evidence to suggest that any particular screening tool is superior. A positive screening test should lead to more extensive evaluation.

The USPSTF recommends screening for depression if staff-assisted depression care supports are in place to ensure accurate diagnosis, effective treatment, and follow-up. If these supports are not in place, screening is not recommended.

Physical examination often reveals injuries in the central area of the body. There may be injuries on the forearms as well if the patient tried to defend herself. As with any situation of expected abuse, bruises that are in various stages of healing may be an important clue. All physical examination findings should be well documented.

In addition to the physical consequences, abuse can have psychological consequences. Posttraumatic stress disorder, depression, anxiety, and alcohol or other substance abuse can develop in victims. Somatization is also very common among victims.

Several instruments have been developed to screen for IPV. These include the HITS (Hurt, Insult, Threaten, Screamed at) tool, the Women Abuse Screening tool (WAST), the Partner Violence Screen (PVS), the Abuse Assessment Screen (AAS), and the Women’s Experience with Battering (WEB) scale. A systematic review of these screening tools showed that most tools only had been evaluated in a relatively small number of studies and the sensitivities and specificities varied widely within and between the tools.

Inclusion of one question in the context of the medical history, “Have you ever been hit, kicked, punched or otherwise hurt by someone within the past year? If so, by whom?” has been shown to increase identification of IPV.

Many studies have addressed how the questions about IPV are asked. In one randomized trial, women preferred written questionnaires over face to face interviewing.

Screening for IPV (in contrast to asking questions when IPV is suspected) has been advocated by many experts, although there is currently no evidence that it improves outcomes. In a randomized controlled trial conducted in emergency departments and other clinical sites, women in the screened group were assessed for IPV and if the screen was positive, the information was given to the clinician before the visit. At 18-month follow-up, there was no difference in recurrence of IPV among women in the screened compared with the non-screened groups. There were also no differences in quality of life, although there were no adverse effects of screening.

The USPSTF has concluded that there is insufficient evidence to recommend for or against universal screening for IPV, since there is currently no evidence that screening improves outcomes. However, clinicians should remain on high alert for clues to IPV among patients.

Interventions for IPV

Interventions can include encouraging the woman to leave the abusive situation, ensuring that she has a safe place to go, and counseling so that she can adequately assess her risk of danger and create a plan for safety. There is no evidence that treatment of the abuser changes abuser behavior.

When to Refer

- Victims should be referred to social services so that they can provide information on local resources. There is a national domestic violence hotline (1-800-799-SAFE) that can provide information on local resources.
- In general, mandatory reporting of IPV or suspicion of it in adult women who are competent is not required in most states. However, mandatory reporting by physicians is required in California, Colorado, Kentucky, Mississippi, Ohio and Rhode Island.

EATING DISORDERS

Eating disorders are common in women. Anorexia nervosa and bulimia nervosa are described in detail in Chapter 29. The female athlete triad, disordered eating in diabetics, and binge eating disorders are other eating disorders that should be considered in appropriate women.

1. Female Athlete Triad

ESSENTIALS OF DIAGNOSIS

- Disordered eating.
- Menstrual disorders.
- Low BMD.

General Considerations

Female athletes who participate in sports and activities valuing thinness are at increased risk for developing the female athlete triad. The definition of the triad includes disordered eating (a spectrum of abnormal patterns of eating, including bingeing; purging; food restriction; prolonged fasting; and the use of diet pills, diuretics, or laxatives), menstrual disorders, and low BMD. Half of all athletes with amenorrhea have bone density at least 1.0 standard deviation below the mean. The bone density is decreased even in those areas subjected to stress during exercise. The diagnosis is made when the individual meets the three criteria of the triad.

Clinical Findings

A. Symptoms and Signs

Individuals with the female athlete triad display some pattern of disordered eating and have some menstrual irregularities. Many women have amenorrhea but others have irregular menses. Typically, the patient has concerns about weight and body image. A history of stress fractures should also raise the clinician’s concern.

B. Laboratory Findings

Depending on the severity of the symptoms and whether or not the patient is bingeing and purging, the laboratory
abnormalities can be similar to those seen in anorexia nervosa or bulimia nervosa. BMD, if measured, is decreased.

**Differential Diagnosis**

The main differential diagnoses include anorexia nervosa, bulimia nervosa as well as endocrine disorders such as hyperthyroidism and diabetes mellitus.

**Treatment**

Little evidence is currently available about treatment of the female athlete triad. Strategies such as counseling, cognitive behavior therapy, and possibly exercise restriction may be helpful. A multidisciplinary approach, including consultation with a nutritionist and communication with the coach and trainers, may enable common goal setting. The desire to participate in sports and the lure of a performance enhancing diet may motivate some patients to pursue treatment.

**2. Disordered Eating in Diabetics**

- **Essentials of Diagnosis**
  - Binge eating.
  - Purging with laxatives or vomiting.
  - Insulin omission.
  - Taking less insulin than prescribed to lose weight.

- **General Considerations**

  Eating disturbances have been estimated to be present in up to one-third of young women with diabetes. Eating disorders are more common in adolescents with diabetes than in their non-diabetic peers. Mortality is particularly high in individuals with both diabetes and eating disorders.

  For diabetes, the dietary regimen emphasizes intense meal timing and consistency. In addition, the hunger associated with hypoglycemia encourages binge eating. Finally, weight gain is often associated with good glycemic control. Diabetics with disordered eating have been shown to have an increased risk of retinopathy. Given the emphasis that young women often place on body weight, maintaining optimal diabetes control is a particular challenge. The diagnosis is typically made in a diabetic who has worsening diabetic control, when other causes of worsening control have been ruled out.

- **Clinical Findings**

  **A. Symptoms and Signs**

  Diabetics may report polydipsia, polyuria, or weight loss. In addition, upon questioning, they may report disturbed eating patterns. Other symptoms associated with eating disorders, such as disturbance of body image and menstrual irregularities, may also be present.

**B. Laboratory Findings**

The main laboratory finding will be a trend of increasing levels of hemoglobin A1C.

**Differential Diagnosis**

The main differential diagnosis includes looking for other causes of worsening glycemic control such as underlying infection or metabolic disease such as hyperthyroidism.

**Treatment**

There is currently no evidence to support any particular strategies for the treatment of disordered eating in diabetic patients. Proposed strategies for at risk diabetic patients include nutritional counseling to promote healthy eating instead of dietary restraint, regular (instead of fixed) meal and snack times, less intensive insulin therapy to reduce weight gain, and family counseling to improve communication.

No studies have evaluated the optimal treatment of diabetic patients with established eating disorders. Presumably, strategies that are effective for patients without diabetes, such as cognitive behavioral therapy and medications, will be effective.

Additional diabetic management strategies that do not require the patient to constantly think about food may be beneficial.

**3. Binge Eating Disorder**

- **Essentials of Diagnosis**

  - Binge eating disorder consists of episodes of eating a large amount of food in a discrete period of time with a sense of lack of control.
  - Binge episodes characterized by at least three of the following:
    - Eating large amounts of food when not feeling hungry.
    - Eating more rapidly than normal.
    - Eating until feeling uncomfortably full.
    - Eating alone because of embarrassment about the amount of food consumed.
    - Feeling disgusted, depressed, or guilty after eating.
  - Episodes occur at least two times a week for at least 6 months.
  - No compensatory behavior (purging, fasting, or excessive exercise) after eating.

Binge eating disorder is more common than either anorexia nervosa or bulimia nervosa, but it is currently not recognized as a psychiatric diagnosis. Currently, the Diagnostic and Statistical Manual of Mental Disorders, fourth edition (DSM-IV) has criteria that are considered research criteria. Individuals who meet these criteria are defined as having eating disorder, not otherwise specified.

Binge eating disorder is much more common in women and is associated with obesity, although not all individuals with binge eating disorder are obese. Obesity-related complications are likely to occur, and the disorder may be more common in weight cycling patients.

### Clinical Findings

The patient may present with weight gain or may describe disordered eating patterns and binge eating episodes. There are no specific laboratory findings for binge eating disorder.

### Differential Diagnosis

The main differential diagnosis includes other psychiatric and eating disorders. Other diagnostic possibilities include hypothyroidism and Prader-Willi syndrome.

### Treatment

Treatment goals focus on decreasing the patient’s binge eating episodes and may include weight loss and treatment of other psychiatric comorbidities. As in bulimia nervosa, cognitive behavioral therapy is the mainstay of treatment. Interpersonal therapy has also been shown to be effective. Pharmacotherapy with selective serotonin reuptake inhibitors is also helpful, but does not appear to be better than cognitive behavioral therapy.

---

**Sexual Health**

Sexual health is defined by the World Health Organization as a state of physical, emotional, mental, and social well-being in relation to sexuality. Healthy sexual functioning therefore depends on a complex interplay of physical, psychological, and societal factors. In the United States, sexual dysfunction is common, with more than 44% of surveyed women reporting a sexual problem and 12% experiencing distress from the problem. Six female sexual disorders have been identified in the DSM-IV and include hypoactive sexual desire disorder (HSDD), sexual aversion disorder, female sexual arousal disorder, female orgasmic disorder, dyspareunia, and vaginismus; these are discussed in detail in Chapters 18 and 25. Notably, HSDD is most prevalent in middle-aged women. Several psychological and biological risk factors can contribute to female sexual dysfunction, including poor mental health, relationship difficulties, and hormonal changes that are associated with aging. In contrast, positive feelings about the partner and the relationship can be “protective.” Physicians should routinely assess patients’ sexual health during office visits; even a brief assessment provides patients with reassurance that this is an important topic. Providers can broach the subject using a broad question, such as “What concerns or questions do you have about your sexual functioning?” and then follow-up with more specific questions, including “Do you have difficulty with desire, arousal, or orgasm?” and “If you are not currently sexual, are there any particular problems that are contributing to your lack of sexual behavior?” Patient concerns can then be delineated more fully during the complete sexual assessment, which encompasses details about medical, surgical, and psychiatric problems, as well as medications and reproductive history. Treatment options depend on the diagnosed disorder and can include psychosexual and hormonal therapy (see Chapter 18).

---

**General Considerations**

Noncyclic pain.

Duration of 6 months or more.

Localized to anatomic pelvis, anterior abdominal wall at or below the umbilicus, the lumbosacral back, or buttocks.

Associated with functional disability.

---

**Chronic Pelvic Pain**

**General Considerations**

Chronic pelvic pain is defined as noncyclic pain lasting at least 6 months that localizes to one of the following areas: the anatomic pelvis, the anterior abdominal wall at or below the umbilicus, the lumbosacral back, or buttocks. It must be of sufficient severity to cause functional disability or necessitate medical care. Endometriosis is diagnosed in up to two-thirds of women with chronic pelvic pain; other common etiologies include postoperative pelvic adhesions, pelvic varices, interstitial cystitis (IC), and...
irritable bowel syndrome (IBS). Musculoskeletal disorders such as fibromyalgia and levator ani syndrome have also been linked to chronic pelvic pain. Women with a history of physical and sexual abuse, pelvic inflammatory disease, abdominopelvic surgery, or difficult obstetric deliveries are at increased risk for developing chronic pelvic pain.

**Clinical Findings**

### A. Symptoms and Signs

Certain features of the history and physical examination can provide clues to the underlying diagnosis. Patients should be asked about the location, quality, and intensity of their pain as well as the relationship with the menstrual cycle, sexual activity, urination, and defecation. Endometriosis, IC, and IBS may all worsen with hormonal changes, resulting in more pain during menses. Dysmenorrhea and dyspareunia are often experienced by patients with endometriosis, whereas dysuria, urgency, and frequency in association with pelvic pain are characteristic of IC. Pain related to pelvic varices is usually postural, worsening with prolonged standing and improving with leg elevation. Patients with IBS often report abdominal pain, distention, and diarrhea or constipation. The physical examination, including the pelvic examination, is usually quite painful in the patient with chronic pelvic pain and should be done carefully. A single-digit internal vaginal examination should be done to localize the exact area of pain and to assess for trigger points along the pelvic floor muscles, which may indicate a musculoskeletal etiology for the pain. Tenderness with palpation of the anterior vaginal wall is consistent with IC, whereas discomfort with palpation of the cervix is suggestive of endometriosis or chronic pelvic infection. Women with pelvic congestion related to varices may have significant uterine tenderness. The external genitalia should also be examined carefully to identify areas of vulvar discomfort because vulvodynia often coexists in patients with chronic pelvic pain. Notably, the absence of physical examination findings does not rule out significant pathology.

### B. Laboratory Findings

Laboratory studies are useful if the history and physical examination do not identify an underlying cause for the pelvic pain. Laboratory tests can include a complete blood count, serum chemistry, erythrocyte sedimentation rate, urine microscopy and culture, and vaginal swabs for detecting chlamydia and gonorrhea.

### C. Diagnostic Testing and Imaging

Pelvic ultrasonography is useful for investigating any abnormalities detected on physical examination, for screening patients in whom pelvic varices are suspected, and for providing reassurance to the patient if the ultrasound is normal. Additional testing may be done to confirm a suspected diagnosis. Patients with IC often have a positive intravesical potassium chloride test or abnormalities detected on cystoscopy. Laparoscopy may be helpful for diagnosing endometriosis or pelvic adhesions, although 40% of diagnostic laparoscopies are normal in patients with chronic pelvic pain.

**Differential Diagnosis**

Chronic pelvic pain is frequently a manifestation of another disease, as noted above. The history, physical examination, and diagnostic testing should be directed toward identifying patients with the most common “benign” underlying conditions, including endometriosis, pelvic adhesions, pelvic varices, IC, and IBS. Clinicians should be aware that patients frequently have more than one diagnosis contributing to the chronic pelvic pain syndrome. Less common but serious causes of chronic pelvic pain should also be considered in the differential diagnosis, including bladder malignancy, colon cancer, endometrial cancer, and inflammatory bowel disease. Accordingly, symptoms such as unexplained weight loss, hematochezia, and abnormal vaginal bleeding should be investigated thoroughly. Many patients have no clear pathologic basis for their symptoms, and are thus diagnosed with idiopathic chronic pelvic pain.

**Treatment**

### A. Medical Treatment

Medical treatment may focus on managing the chronic pain, the underlying condition, or both. Analgesics are commonly used, and nonsteroidal anti-inflammatory drugs (NSAIDs), such as diclofenac and naproxen, are typically helpful. However, patients and clinicians should be cautious about long-term use of these medications because long-term NSAID therapy can be associated with significant gastric toxicity. Antidepressants (eg, amitriptyline) and antiseizure medications (eg, gabapentin) (see Table 5–5), which have demonstrated efficacy in the treatment of other pain syndromes, may also be useful for chronic pelvic pain. Opioid therapy improves pain but not functional or psychological outcomes and should generally be avoided.

Hormonal therapies are used primarily for treating gynecologic sources of chronic pelvic pain. Women with endometriosis often benefit from treatment with combined oral contraceptive pills, which suppress ovulation and reduce dysmenorrhea. Gonadotropin-releasing hormone (GnRH) agonists and progestins improve pain associated with endometriosis and pelvic varices. The decrease in BMD associated with GnRH agonist treatment can be mitigated with estrogen or progesterone add-back therapy. Patients in whom endometriosis is suspected may also be treated with GnRH agonist therapy; improvement in symptoms may allow such patients to avoid laparoscopy.

Medical therapies directed at the treatment of nongynecologic sources of chronic pelvic pain, including IC and IBS, are discussed in Chapters 15 and 23. Notably, pelvic pain associated with IC and IBS frequently varies with the menstrual cycle, and GnRH agonist therapy may be helpful for treatment in these disorders as well.
Physical therapy and injection of identified trigger points provide significant pain relief in patients with musculoskeletal sources of pain. Sacral nerve stimulation has been used in patients with IC but may also be effective in up to 60% of women with chronic pelvic pain but without urinary symptoms. Psychological evaluation and treatment should also be strongly considered in all patients, both to improve treatment outcomes (particularly in patients with pelvic varices) as well as to address a history of sexual or physical abuse.

B. Surgical Treatment

Surgical treatment of chronic pelvic pain requires referral to a gynecologist. Surgical therapies that treat the pain itself include presacral neurectomy and laparoscopic uterosacral nerve ablation. These denervating interventions are typically used in the treatment of patients with severe dysmenorrhea. Condition-specific surgical treatments include adhesiolysis in patients with pelvic adhesions and laparoscopic surgical destruction of implants in patients with endometriosis. Importantly, the efficacy of adhesiolysis in the treatment of chronic pelvic pain is controversial. Hysterectomy can be effective for relieving chronic pelvic pain and may also result in improved psychological and sexual outcomes.

Prognosis

Cohort studies provide some information on the prognosis of women who undergo hysterectomy as definitive treatment for chronic pelvic pain. In a comparative study of women with chronic pelvic pain, abnormal uterine bleeding, or leiomyomas, women who had a hysterectomy experienced significant improvement in symptoms compared with those treated medically after 1 year. However, among younger patients with chronic pelvic pain who do not have obvious anatomic pathology, the benefits of surgery are less clear, and up to 40% of patients may still have persistent pain after hysterectomy.

When to Refer

Patients should be referred to a gynecologist for diagnostic or therapeutic surgical procedures, if the underlying diagnosis is unclear, or if the provider feels uncomfortable managing side effects associated with medical treatments (ie, GnRH agonist therapy).

MSTALGIA

General Considerations

Breast pain, or mastalgia, is categorized as cyclical, noncyclical, or extramammary. Although minor breast discomfort is commonly associated with the normal menstrual cycle, women with cyclical mastalgia typically have moderate to severe pain that can last more than 5 days. Cyclical mastalgia can be diagnosed only in reproductive-age women who experience breast pain as a result of the hormonally-mediated proliferation in breast tissue that occurs with ovulation. In contrast, noncyclical mastalgia has no relationship to the menstrual cycle and can occur in premenopausal or postmenopausal women. Causes of noncyclical mastalgia include large breast size (with stretching of Cooper ligaments), medications, pregnancy, thrombophlebitis, or inflammatory breast cancer. Extramammary mastalgia is caused by pain that is referred from other anatomic locations, including the chest wall, heart, gallbladder, or spine. Trauma or previous surgery may also produce extramammary pain.

Clinical Findings

A. Symptoms and Signs

Cyclical mastalgia is often described as a deep, heavy, aching pain, which is typically diffuse and bilateral and is clearly associated with the menstrual cycle. Conversely, noncyclical pain, which may be constant or intermittent, is often well localized and can involve one or both breasts. Chest wall pain, a frequent cause of extramammary mastalgia, typically causes unilateral, burning pain that may be either localized or diffuse. Malignancy-associated mastalgia is often severe, progressive, and unilateral.

Breast cancer may be associated with mastalgia, and thus a careful physical examination is essential in all women who report breast pain. Large, pendulous breasts may be observed in women who have noncyclical pain caused by stretching of Cooper ligaments. Chest wall pain is usually related to inflammation or injury to the pectoralis major muscle; it may be reproduced by palpation or by having the patient place her hand on her hip and push inward. Any palpable breast mass must be evaluated further with radiologic imaging.
B. Imaging
An ultrasound or mammogram or both should be obtained in women who have a palpable breast mass. Clinicians should also ensure that patients with mastalgia are up to date on routine screening mammography, as appropriate for their age and personal risk factors.

Differential Diagnosis
Malignancy must be ruled out in all patients with mastalgia, and this is usually accomplished through a careful history, physical examination, and diagnostic imaging in patients with clinical abnormalities, such as a palpable breast mass. Extramammary causes of breast pain include chest wall pain, spinal or gallbladder disease, and myocardial ischemia. Cyclic and noncyclical mastalgia are easily differentiated by assessing the temporal relationship between the patient’s pain and her menstrual cycle.

Treatment
Women with cyclical mastalgia who have a normal physical examination and are up to date on routine mammographic screening should be reassured about the benign nature of their symptoms and monitored closely. Cyclic and noncyclical mastalgia often improve with use of a supportive bra. Although there is conflicting evidence regarding the benefit of vitamin E, some experts advocate its use (at a dose of 2000–3000 mg daily) for women with cyclical breast pain. Topical NSAIDs, such as diclofenac gel, improve localized breast pain.

Women who experience severe and persistent cyclical mastalgia despite adherence to conservative measures may be offered hormonal treatment. Commonly used hormonal therapies for cyclical mastalgia include danazol, bromocriptine, and tamoxifen. Danazol, a synthetic androgen that inhibits ovulation, is the only medication that has been approved by the Food and Drug Administration (FDA) for the treatment of cyclical mastalgia. However, side effects associated with treatment are common and include weight gain, menstrual irregularities, voice deepening, and hot flashes. Similarly, in a study of patients with cyclical mastalgia who were treated with bromocriptine, 40% of patients experienced adverse reactions, including nausea, dizziness, and headache. Tamoxifen therapy is tolerated well by most women, and many experts recommend it as first-line therapy for the treatment of cyclical mastalgia. Patients treated with tamoxifen should be counseled about the possibility of hot flashes and menstrual irregularities (experienced by up to 10% of women), as well as the risk for more serious adverse events, such as thromboembolic disease and endometrial cancer.

Prognosis
Symptoms of cyclical and noncyclical mastalgia improve without pharmacologic treatment in most women. In addition, most women with cyclical mastalgia have resolution of their pain with menopause. Observational studies examining the association between cyclical mastalgia and the subsequent development of breast cancer have produced conflicting results. Two case-control studies suggested an increased risk of breast cancer, while a third observational study suggested a decreased risk. Based on this evidence, guidelines indicate that all women with mastalgia should have an individual assessment of their breast cancer risk, and that this should guide subsequent management.

Women in whom mastalgia develops while receiving hormone replacement therapy may have an increased risk of breast cancer. In a recent analysis of data from the Women’s Health Initiative, women in whom new-onset breast tenderness developed after initiating treatment with conjugated equine estrogen plus medroxyprogesterone had a 48% higher risk of developing breast cancer compared with those who did not experience breast pain. Thus, women in whom mastalgia develops in the setting of hormone-replacement therapy should have a thorough discussion with their clinician regarding the risks and benefits of continued treatment as well as screening and preventative strategies for breast cancer.

When to Refer
Patients with mastalgia and a palpable breast mass should be referred to a breast surgeon, even if the results of diagnostic imaging are normal.

THE PALPABLE BREAST MASS

Diagnostic imaging is essential for any women with a palpable dominant breast mass, regardless of her age.

Ultrasound is the initial test of choice for women under the age of 30; diagnostic mammography with or without ultrasonography is performed initially in women over the age of 30.

General Considerations
Palpable breast masses may be detected by a patient on a breast self-examination, or may be identified by the provider during a routine physical examination. Approximately 10% of breast masses are malignant, and thus a thorough work-up of any palpable breast mass is essential, regardless of age and personal risk factors for breast cancer.
Common benign causes of palpable breast masses include fibrocystic condition, cysts, and fibroadenomas (see also Chapter 17).

Clinical Findings

A. Symptoms and Signs

Clinicians should ask patients about temporal changes in the mass shape and size, as well as associated symptoms, including pain, skin thickening, and nipple discharge. A patient’s personal risk for breast cancer should be assessed, including age, previous breast biopsies, family history, and age at menarche and first pregnancy.

The location of the mass should be described using the clock-face position and distance from the nipple, as this aids the radiologist in the diagnostic evaluation. Examiners should also note the size, site, mobility, and texture of the mass, as well as areas of skin dimpling, retraction, or erythema. Benign masses are typically mobile with well-defined margins; conversely, malignant lesions may be fixed and have indistinct borders. Some women may have areas of indeterminate thickening in the absence of a discrete and well-defined palpable mass; if this finding is asymmetric it should be evaluated further with diagnostic imaging.

B. Diagnostic Tests and Imaging

As noted above, all women with a dominant palpable breast mass require diagnostic imaging. Approved imaging techniques include diagnostic mammography and ultrasonography. Diagnostic mammography consists of the standard views that are used in screening mammography, plus additional views, such as spot-compression and magnification, to better delineate the area of concern. The breast ultrasound is the most sensitive test for distinguishing a cystic from a solid lesion, and also provides detailed information regarding the shape, borders, and acoustic properties of an identified mass. In addition, ultrasonography can be used to guide the biopsy of suspicious lesions.

Women over the age of 30 with a palpable breast mass should initially be evaluated with diagnostic mammography. Features of a benign lesion include a round shape with well-circumscribed borders; a suspicious finding may have an irregular shape with spiculated margins. Ultrasonography may be coupled with diagnostic mammography if the mass is mammographically occult or has concerning mammographic features. For women under the age of 30, ultrasonography is the initial diagnostic test of choice because the dense breast tissue found in younger women limits the sensitivity of mammography. Abnormal findings on ultrasound include posterior acoustic shadowing, microlobulations, and a spiculated margin. A mass which has a thin, echogenic capsule, an ellipsoid shape, and homogenous echogenicity is more likely to be benign.

In women who are pregnant, ultrasonography is the initial diagnostic test of choice; the sensitivity of mammography is limited by the loss of contrasted fatty tissue in the breast during pregnancy. Fine-needle aspiration (FNA) biopsy does not have the same accuracy in pregnant women as a result of the increased cellularity of the breast tissue, and breast biopsy may be technically difficult because of increased breast vascularity. Surgical consultation should be obtained to evaluate persistent areas of concern that are identified on clinical breast examination and ultrasound.

Differential Diagnosis

The differential diagnosis of palpable masses includes benign etiologies, such as cysts, fibroadenomas, fibrocystic condition, lymph nodes, galactoceles, lipomas, and hematomas. Breast cancer, including ductal carcinoma in situ, invasive lobular carcinoma, and invasive ductal carcinoma, can also initially present with a palpable breast mass. Certain history and physical examination features may be suggestive of a particular diagnosis. Cysts are fluid-filled structures that are commonly found in women aged 35–50 years; acute enlargement of the cysts may cause abrupt and severe pain. Fibroadenomas are typically diagnosed in reproductive age women between the ages of 15 and 35 years and present as firm, nontender, and mobile masses on physical examination. Fibrocystic condition describes a pathologic diagnosis that may be accompanied by clinical symptoms and signs, including cyclical pain that is bilateral and poorly localized as well as tender, multifocal nodules. These fibrocystic changes, which include macrocysts, microcysts, fibrosis, and ductal hyperplasia, are most common among premenopausal women.

Treatment

Management of the palpable breast mass depends on the results of diagnostic imaging. If ultrasonography or mammography suggests that the mass is related to a simple cyst, fine-needle aspiration (FNA) may be offered to symptomatic women to relieve associated pain. Characteristics of the aspirated fluid guides further work-up. If benign fluid, which is typically yellow, straw-colored, green, or brown, is aspirated and the mass resolves, the patient can be monitored expectantly. Conversely, if bloody fluid is aspirated, or if the mass persists after aspiration, further intervention with either core biopsy or excision may be indicated. A complex cyst should always be aspirated because there is a small chance (0.4%) that it may be malignant.

Core-needle biopsy, which provides a sample of tissue for histologic diagnosis, is typically used to evaluate breast masses that have a suspicious appearance on diagnostic imaging. Ultrasonography, mammography, or MRI may be used to guide the biopsy, thereby resulting in few complications and minimal trauma to the breast tissue. Excisional biopsy may be necessary if the mass is not amenable to core-needle biopsy (because of location or imaging characteristics) or if additional tissue is needed to confirm a benign diagnosis.

Women who have palpable masses that are associated with normal ultrasound or mammographic imaging should be referred to a breast surgeon, with consideration given to performing a diagnostic core-needle biopsy. Benign biopsy results are reassuring but require close clinical follow-up for at least 1–2 years.

The radiologist may categorize certain breast masses as probably benign after review of ultrasound or mammographic
images. In rare cases, these masses may be associated with malignancy, and so two diagnostic options may be considered. The patient may opt to forgo biopsy at that time and have imaging performed again in 6 months. Alternatively, diagnostic core excisional biopsy may be performed immediately (after consultation with a breast surgeon) if there are worrisome findings on physical examination or if there is a high clinical suspicion for malignancy. All masses categorized as probably benign require follow-up imaging at 6-month intervals for at least 2 years.

The “triple test,” which is composed of the findings on physical examination, the results of diagnostic imaging, and the pathologic diagnosis obtained from FNA or core-needle biopsy, helps clinicians determine the likelihood that a palpable breast mass is malignant. In all cases, the results of each of these tests should be concordant. For example, the diagnostic imaging should identify the palpable area of concern, and if benign features are noted, the results of the FNA biopsy or core-needle biopsy should confirm a benign diagnosis, such as a fibroadenoma. If the results of any of the tests are discordant, further evaluation is warranted. Thus, if the results of FNA biopsy or core-needle biopsy suggest a benign diagnosis, but the radiographic imaging indicates a suspicious lesion, it may be appropriate to repeat the biopsy or perform an excisional biopsy. Similarly, if there is a palpable breast mass that is not identified on radiographic imaging, referral to a breast surgeon is necessary to document resolution or persistence of the mass. If the mass is persistent, the surgeon may elect to perform a biopsy to obtain a definitive diagnosis.

Prognosis

In general, the benign causes of a palpable breast mass have a favorable prognosis. Many women with breast pain and palpable masses due to fibrocystic condition have spontaneous resolution or have improvement in their symptoms with menopause. Benign simple cysts that are asymptomatic may be followed clinically, and symptomatic cysts should resolve with aspiration.

Certain pathologic diagnoses increase the risk of breast cancer, including papillary lesions, radial scars, atypical ductal or lobular hyperplasia, and lobular carcinoma in situ. FNA biopsy or core-needle biopsy results that indicate one of these diagnoses necessitate referral to a breast surgeon for further evaluation and management.

When to Refer

• Women with a palpable breast mass should be referred to a breast surgeon in the following situations:
  – If diagnostic imaging indicates that the mass has suspicious features.
  – If the mass persists and diagnostic imaging is normal.
  – If the mass is categorized as probably benign on diagnostic imaging, but there are worrisome features on physical examination or there is a high clinical suspicion for malignancy.
  – If diagnostic imaging demonstrates a complex cyst, or aspiration of a simple cyst reveals a bloody aspirate.
  – If the biopsy demonstrates a lesion with an increased risk of breast cancer (papillary lesions, radial scars, atypical hyperplasia, lobular carcinoma in situ).
  – If the biopsy results are discordant with the physical examination and radiographic findings.

• It may also be prudent to refer pregnant women with a palpable breast mass to a breast surgeon, because of the limitations noted above with radiographic imaging and biopsy.

NIPPLE DISCHARGE

Nipple discharge is a common breast complaint but is rarely indicative of malignancy. In one retrospective study, invasive breast cancer was subsequently diagnosed in only 5% of women in whom nipple discharge was the presenting symptom. Nipple discharge that comes from multiple ducts, is bilateral, and is produced only with squeezing is considered physiologic, and no further work-up is necessary. Milky discharge that is bilateral and spontaneous is consistent with galactorrhea caused by an elevated prolactin level. Investigation should focus on identifying the underlying causes of the hyperprolactinemia, including pregnancy, pituitary tumors, and certain medications. Women who have bloody discharge or persistent spontaneous unilateral discharge from a single duct, should be referred for mammography and surgical consultation. These features are suggestive of a pathologic diagnosis, such as papilloma, duct ectasia, or malignancy. In addition, the presence of a palpable breast mass in association with the nipple discharge significantly increases the likelihood of underlying malignancy. Surgical excision of the involved duct is the gold standard for diagnosis. See also Chapter 17.

FEMALE PATTERN HAIR LOSS

Androgenetic alopecia, also known as female pattern hair loss, is the most common cause of alopecia in women; up to 50% of females will be affected in their lifetime. This type of alopecia is mediated by the effects of androgen on the hair follicle and is characterized by shortening of the anagen (growth) phase and follicle miniaturization. Clinically, presenting signs include diffuse thinning over the central scalp and a prominent midline part; the frontal
hairline is typically preserved. Although serum androgen levels are typically normal, androgen excess disorders can present with female pattern hair loss. If irregular menses, hirsutism, or acne accompany the female pattern hair loss, the patient should be evaluated for an underlying hyperandrogenic condition with measurements of total and free testosterone, prolactin, and dehydroepiandrosterone.

Topical minoxidil is currently the only medication that has been approved by the FDA for the treatment of female pattern hair loss. Randomized trials have confirmed the efficacy of this therapy, compared with placebo, for inducing minimal to moderate hair regrowth in the majority of treated women (NNT = 8). In patients with suspected female pattern hair loss, minoxidil 2% is applied directly onto the scalp twice daily while symptoms persist. The most common side effect of minoxidil is facial hypertrichosis, which can affect 3–5% of women, but this typically resolves after 1 year of treatment. In women who have excess androgen levels, the addition of spironolactone (an anti-androgen) to minoxidil treatment may result in additional clinical benefit. Similarly, an oral contraceptive pill containing drosperrone, which is a spironolactone analogue, is an appropriate choice in women desiring hormonal contraception.

**TREATMENT OF VARICOSE VEINS**

Varicose veins result from weakness in the vein wall and may involve obstruction to, or reversal of, normal blood flow. Approximately 30–40% of women are affected, and the clinical presentation ranges from asymptomatic to severe, with lower extremity pain, swelling, and nocturnal cramps. Medical complications can include venous ulceration, abnormal skin pigmentation, and eczema.

Treatment may be considered to relieve symptoms or for cosmetic purposes. Conservative therapy is generally recommended for asymptomatic patients or those who experience only mild to moderate discomfort. The principle behind conservative therapy is to limit disease progression: weight loss and physical exercise will improve circulation, and avoidance of prolonged standing will reduce the pressure on affected valves. Compression stockings improve venous hemodynamics and reduce symptoms of pain and swelling.

Invasive therapy may be indicated to treat patients with more severe symptoms, or those who desire significant cosmetic results. The gold standard for treating varicose veins is surgical ligation and vein stripping. If the greater saphenous vein is involved, both ligation and stripping are typically performed; smaller saphenous veins may be treated only with ligation. Surgical techniques are effective in the short-term, but recurrence is common, ranging from 30% to 50% after 5 years. Moreover, patients who receive surgical therapy are exposed to the risks of general or epidural anesthesia and may experience postoperative pain and neurologic damage.

Minimally invasive techniques for treating varicose veins have been increasing in popularity and are often associated with faster recovery times and fewer complications when compared with surgical treatment. Currently available therapies include ultrasound-guided foam sclerotherapy (UGFS), radiofrequency ablation (RFA), and endovenous laser ablation (EVLA). Sclerotherapy is usually done in the ambulatory setting and involves injecting a chemical through a catheter into the abnormal vein to induce scarring and collapse. UGFS mixes air or gas with the sclerosing substance to produce foam, which allows for coverage of a larger surface area. Injection sclerotherapy is most beneficial for small and medium-size veins; rare complications include embolization of foam to the brain or retina. RFA and EVLA both use the principles of thermolysis to selectively induce vessel-wall damage and collapse. Laser (EVLA) or radiofrequency (RFA) energy is used to generate a heated fiber, which is inserted into the abnormal vein and slowly advanced along its length. Endothelial and vessel wall damage results, with contraction of the vein wall and ultimate collapse of the entire vessel. A minority of patients may experience local bruising, tenderness, or paresthesias as a result of these procedures.

Meta-analysis evaluating the efficacy of each of these techniques compared with surgical intervention demonstrated that success rates, as measured by complete obliteration of the vessel at 5 years, were highest for EVLA and RFA (95.4% and 79.9%, respectively) and were similar for UGFS and surgery (73.5% and 75.7% respectively). Moreover, the efficacy of RFA, UGFS, and surgery declined substantially over time, but remained relatively constant for EVLA. The authors of this study concluded that EVLA was the most effective of the minimally invasive techniques and was associated with fewer side effects and faster improvement in health-related quality of life when compared with surgical therapy. However, more studies that directly compare these methods to each other are needed.

**AGE-RELATED FACIAL CHANGES**

Minimally invasive aesthetic procedures are now commonly used to treat mild to moderate age-related changes in the face. These procedures are generally safe and are associated with high rates of patient satisfaction. In 2008, more than 80% of aesthetic plastic surgery treatments involved minimally invasive techniques. Thus, primary care clinicians should be familiar with the efficacy and safety of these treatment modalities in order to best counsel their patients.
Visible signs of aging in the face result from loss of subcutaneous fat, gravitational changes, and alterations in skin elasticity. Various areas of the face respond differently to each of these changes and at different times. In the upper one-third of the face, hyperdynamic wrinkles, manifested as frown lines, crow’s feet, and horizontal forehead lines, typically develop as a result of repetitive muscle contraction. Conversely, volume changes are more prominent in the mid-face, as gravitational descent of the malar fat pad and volume loss leads to deepening of the nasolabial folds. Changes in the lower one-third of the face are characterized both by hyperdynamic changes resulting in deep furrows and lines, as well as flattening and loss of fullness in the lips.

_Clostridium botulinum_ is an organism that produces potent neurotoxins with various serotypes, ranging from A to G. These serotypes vary in both their mechanism of action and clinical use, and only serotype A is used for cosmetic purposes. Botox and Dysport are two formulations of botulinum serotype A that the FDA has approved for treating hyperactivity of the glabellar muscles, which produces frown lines. Both of these products work by inhibiting the release of acetylcholine at the neuromuscular junction, thereby resulting in a chemical denervation and an overall relaxation of hyperdynamic facial muscles. Botox and Dysport are also commonly used off-label to treat horizontal frown lines and crow’s feet, as the restriction of muscular movement in these areas also reduces the appearance of fine wrinkles. The onset of action of these treatments is immediate, and results typically last 3–4 months. In one study, only 5% of studied patients who had been treated with Botox experienced adverse effects, the most common of which was local bruising.

Whereas Botox and Dysport are the treatments of choice in the upper one-third of the face to treat fine wrinkles, dermal fillers are commonly used in the mid- and lower face to restore volume and fullness. Several filler substances are currently used, including collagen, hydroxylapatite, hyaluronic acid, and injectable poly-L-lactic acid. Among these, hyaluronic acid fillers have become increasingly popular and have been approved by the FDA for treatment of nasolabial folds. They are also frequently used off-label to volumize and shape the lips. Several formulations are currently available, and they differ in their degree of cross-linking, gel hardness, and ability to resist dilution. Clinically, these differences result in various degrees of longevity, with the effects of Restylane and Perlane lasting approximately 6 months, and the effects of Juvederm Ultra and Juvederm Ultra Plus lasting approximately 12 months. The effects of injection are immediately apparent, and complications are typically mild and local, including bruising, redness, and swelling. If necessary, the injection of hyaluronidase can reverse any significant adverse effects. Notably, the clinical improvement associated with hyaluronic acid injections seems to be closely associated with the expertise of the practitioner.

Combination therapy with botulinum toxin and hyaluronic acid is now commonly being used to achieve more satisfying cosmetic results. However, serious complications can result from the injection of hyaluronic acids in the upper face, including skin necrosis, which occurs when the injection inadvertently involves a blood vessel. A thorough knowledge of the anatomy in this area is essential for avoiding this adverse event. Similarly, only experienced practitioners should use botulinum toxin in the lower face, to avoid the drooling, speech problems, and mouth incompetence that result from over-injection or misplaced treatment.

## Appendix: Therapeutic Drug Monitoring, Pharmacogenetic Testing, & Laboratory Reference Intervals

C. Diana Nicoll, MD, PhD, MPA  
Chuanyi Mark Lu, MD, PhD

### Table 1. Therapeutic drug monitoring.\(^1\)

<table>
<thead>
<tr>
<th>Drug</th>
<th>Effective Concentrations</th>
<th>Half-Life (hours)</th>
<th>Dosage Adjustments</th>
<th>Comments</th>
</tr>
</thead>
</table>
| Amikacin    | Conventional dosing: Peak: 20-30 mg/L; trough: < 10 mg/L  
High dose once daily: Peak: 60 mg/L; trough: undetectable | 2-3; ↑ in uremia | ↓ in renal dysfunction | Concomitant kanamycin or tobramycin therapy may give falsely elevated amikacin results by immunoassay. |
| Amitriptyline | 95-250 ng/mL              | 9-25              |                    | Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted therapeutic reference interval for effective concentration. |
| Carbamazepine | 4-12 mg/L                | 10-15             |                    | induces its own metabolism. Metabolite 10,11-epoxide exhibits 13% cross-reactivity by immunoassay. Adverse reactions: skin reactions, myelosuppression. |
| Cyclosporine | 100-300 mcg/L (ng/mL) whole blood | 6-12              | ↓ in renal dysfunction, liver disease | Cyclosporine is lipid-soluble (20% bound to leukocytes; 40% to erythrocytes; 40% in plasma, highly bound to lipoproteins); the binding is temperature-dependent in vitro and concentration-dependent in vivo. HPLC and LC-tandem mass spectrometry methods are highly specific for parent drug and considered as the gold standard assays. Monoclonal fluorescence polarization immunoassay (FPIA) and monoclonal chemiluminescence immunoassay also measure cyclosporine reliably; polyclonal immunoassays are less specific due to cross-reaction with drug metabolites. Anticonvulsants and rifampin increase metabolism. Erythromycin, ketoconazole, and calcium channel blockers decrease metabolism. The main adverse reaction is concentration-related nephrotoxicity. |
| Desipramine | 100-250 ng/mL             | 13-23             |                    | Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted therapeutic reference interval for effective concentration. |

</table>

(continued)
Sirolimus is an immunosuppressant used in combination with cyclosporine and corticosteroids for prophylaxis of organ rejection after kidney transplantation. It has also been used in liver and heart transplantation. When used in combination with cyclosporine, careful monitoring of kidney function is required.

Once the initial dose titration is complete, monitoring sirolimus trough concentrations weekly for the first month and every 2 weeks for the second month appears to be appropriate.

The optimal time for specimen collection is 24 h after the previous dose or 0.5 to 1 h prior to the next dose (trough level).

Tacrolimus is used for prophylaxis of organ rejection in adult patients undergoing liver or kidney transplantation and in pediatric patients undergoing liver transplantation. It has also been used to prevent rejection in heart, small bowel, and allogeneic bone marrow transplant patients and to treat autoimmune diseases.

Antacid or sucralfate administration should be separated from tacrolimus by at least 2 h.

The optimal time for specimen collection is 12 h after the previous dose or 0.5 to 1 h prior to the next dose (trough level).

<th>Selected Variants (mutant allele, enzyme activity)</th>
<th>Allele Frequency</th>
<th>Drugs</th>
<th>Clinical Relevance</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cytochrome P450 (CYP) 2C9 variants</td>
<td>2C9<em>2 (430C&gt;T, ↓↓) 2C9</em>3 (1075A&gt;C, ↓↓)</td>
<td>2C9<em>2 and 2C9</em>3 are present in 9–20% of whites, 1–3% of blacks, and &lt; 1% of Asians</td>
<td>Warfarin (Coumadin)</td>
<td>Hepatic CYP2C9 is responsible for the metabolic inactivation and clearance of the anticoagulant warfarin. Patients carrying 2C9<em>2 or 2C9</em>3 (or both) (heterozygote, homozygote or compound heterozygote) require reduced maintenance dose to reach a therapeutic INR. While INR remains the standard for monitoring warfarin therapy, CYP2C9 genotyping can be an important aid to dosing strategy for warfarin-naïve patients, particularly whites.</td>
</tr>
<tr>
<td>CYP 2C19 variants</td>
<td>2C19<em>2(681G&gt;A, none) 2C19</em>3(636G&gt;A, none) 2C19<em>4(1A&gt;G, none) 2C19</em>5(1297C&gt;T, none)</td>
<td>The mutant variants are present in 12–25% of Asians, and 2–7% of whites and blacks</td>
<td>Clopidogrel (Plavix)</td>
<td>Clopidogrel, an antiplatelet drug, must be metabolized in the liver by CYP isoenzymes, principally CYP 2C19, to become active. When treated with clopidogrel at recommended dosages, patients with CYP 2C19 variants have more cardiovascular events than do patients with normal CYP 2C19 function. Alternative drug or intervention strategies should be considered for patients with 2C19 variants.</td>
</tr>
<tr>
<td>HLA-B*1502 allele</td>
<td>HLA-B*1502</td>
<td>10–15% of Asians; 1–2% of whites</td>
<td>Carbamazepine (Tegretol, Epitol)</td>
<td>Carbamazepine is associated with serious or even fatal idiosyncratic skin reactions, eg, Stevens-Johnson syndrome and toxic epidermal necrolysis. The reactions are significantly more common in patients who carry the HLA-B<em>1502 allele. This allele occurs almost exclusively in patients with ancestry across broad areas of Asia, including South Asian Indians. HLA-B</em>1502 genotyping may be useful for risk stratification in patients of Asian descent. Patients carrying the HLA-B*1502 allele should not be given carbamazepine unless the expected benefit clearly outweighs the increased risk of serious skin reactions.</td>
</tr>
<tr>
<td>HLA-B*B5701 allele</td>
<td>HLA-B*B5701</td>
<td>6–8% of whites and selected Indians; 1–2% of blacks and Asians</td>
<td>Abacavir (Ziagen)</td>
<td>Abacavir is a nucleoside analog reverse transcriptase inhibitor used for HIV treatment. The major treatment-limiting toxicity for abacavir use is drug hypersensitivity, occurring in 5–8% of recipients within 6 weeks of commencing therapy. There is an established association between carriage of the HLA-B<em>B5701 allele and abacavir hypersensitivity reactions. HLA-B</em>B5701-positive patients should not be prescribed abacavir or an abacavir-containing regimen.</td>
</tr>
</tbody>

<tr>
<th>Pharmacogenetic Biomarker</th>
<th>Selected Variants (mutant allele, enzyme activity)</th>
<th>Allele Frequency</th>
<th>Drugs</th>
<th>Clinical Relevance</th>
</tr>
</thead>
<tbody>
<tr>
<td>Thiopurine methyltransferase (TPMT) variants</td>
<td>TPMT*2 (238G&gt;C, ↓)</td>
<td>About 10–12% of whites and blacks have reduced enzyme activity because they are heterozygous for one of the mutant alleles. About 1 in 300 whites is homozygous for a mutant allele.</td>
<td>Azathioprine (AZA), 6-mercaptopurine (6-MP)</td>
<td>AZA is a prodrug that is metabolized to 6-MP, which is then further metabolized to active 6-thioguanine (6-TG) and inactive 6-methylmercaptopurine (6-MMP) through hypoxanthine phosphoribosyltransferase and TPMT, respectively. Variation in the TPMT gene can result in functional inactivation of the enzyme and an increased risk of life-threatening, 6-TG associated myelosuppression. TPMT genotyping before instituting AZA or 6-MP can help prevent toxicity by identifying individuals with low or absent TPMT enzyme activity. Patients with homozygous or compound heterozygous mutant alleles (&quot;poor metabolizers&quot;) should not be given AZA or 6-MP, while heterozygotes with a single mutant allele should be treated with lower doses.</td>
</tr>
<tr>
<td></td>
<td>TPMT*3A (460G&gt;A and 719A&gt;G, ↓↓)</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>TPMT*3B (460G&gt;A, ↓)</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>

<td>TPMT*3C (719A&gt;G, ↓)</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Uridine diphosphogluconosyltransferase 1A1 (UGT 1A1) variants</td>
<td>UGT1A1*28 (7 TA repeats in promoter, ↓)</td>
<td>Homozygosity in 9-23% of whites, blacks and Indians, and in 1-2% of eastern Asians.</td>
<td>Irinotecan (Camptosar)</td>
<td>Irinotecan is used in the treatment of metastatic colorectal cancer. It is metabolized to active SN-38, a topoisomerase I inhibitor. SN-38 is further glucuronidated to inactive SN-38G by UGT1A1 and excreted. Heterozygous and homozygous UGT1A1<em>28 genotypes show a 25% and 70% decrease in enzyme activity, respectively. The presence of the UGT1A1</em>28 allele is a risk factor for the development of adverse drug reactions (eg, neutropenia, severe diarrhea). Testing for the allele can prevent drug toxicity at high doses of irinotecan.</td>
</tr>
<tr>
<td>Vitamin K epoxide reductase complex (VKORC1) variants</td>
<td>VKORC1 (−1639G&gt;A)</td>
<td>The homozygous (−1639G&gt;A) allele (−1639AA genotype) is present in approximately 15% of whites and 80% of Chinese.</td>
<td>Warfarin (Coumadin)</td>
<td>The primary therapeutic target of the anticoagulant warfarin is VKOR. Polymorphisms in the VKOR encoding gene (VKORC1) explain about 30% of the phenotypic variability in drug effect. Patients carrying the VKORC1 (−1639G&gt;A) allele require a lower warfarin maintenance dose to reach a therapeutic INR.</td>
</tr>
<tr>
<td>Braf gene</td>
<td>Braf V600E mutation</td>
<td>40-60% of advanced melanomas</td>
<td>Vemurafenib (Zelboraf)</td>
<td>Activating mutations in B RAF (a serine-threonine protein kinase) are present in 40-60% of advanced melanomas. Most, with (80-90%) of the mutations are the substitution of glutamic acid for valine at amino acid 600 (V600E mutation), and this is associated with a more aggressive clinical course. Vemurafenib, a potent inhibitor of the mutant B RAF, has a high level of therapeutic activity against advanced melanomas containing the V600E mutation.</td>
</tr>
</tbody>
</table>

1 Testing of these genetic biomarkers prior to instituting drug therapy is now recommended per US Food and Drug Administration-approved drug labels. Note, however, that these tests are not yet mandated as standard practice. ↓, decreased; ↓↓, markedly decreased; >, single wild-type to variant nucleotide switch at the specific gene location; CYP, cytochrome P450 oxidase.

Acyclovir, 1353r
for herpes simplex infections, 118–119, 598, 1280, 1330, 1338r, 1352, 1353r, 1355
Adenomatous polyposis coli. See APC gene
Adenomatous polyposis, 652, 653
colonoscopy/sigmoidoscopy in identification/treatment of, 653, 653–654, 1627–1628, 1628
colorectal cancer and, 653, 654, 655, 1622, 1623, 1626, 1628
familial, 654–655, 1622. See also Familial adenomatous polyposis
FOBT in patients with, 653
gastric, 620–621, 655
nonfamilial, 653–654
Adenomyomatosis
biliary tract/gallbladder, 703r, 705
diabetic ketoacidosis and, 1232, 1235
diarrhea/gastroenteritis, 1293, 1330,
for breast cancer, 735, 736–737, 1611
for bladder cancer, 1639, 1640
for breast cancer, 735, 736–737, 1611t
in older women, 738
for colorectal cancer, 1624, 1625,
for gastric adenocarcinoma, 1617
for lung cancer, 1599–1600
for prostate cancer, 1635
for renal cell carcinoma, 1641
Adjuvant pain medications/treatments, 85
ADL–IADL. See Activities of daily living–instrumental activities of daily living
Adnexal masses. See Ovarian cancer/tumors
Adnexectomy, for tubo-ovarian abscess, 764
Adolescents, immunization recommendations for, 1307
ADPKD1/ADPKD2 genes, 934
Adrenal cortex
diseases of, 1154–1166. See also specific disorder
in hypopituitarism, 1093, 1094, 1095
in HIV infection/AIDS, 1157, 1330
hyperplasia of
doosteronism caused by, 438, 1164, 1165, 1166
congenital, 1156, 1163
Cushing syndrome caused by, 1158
hirustam/virilization and, 1163
in MEN, 1189
hypoplasia of, congenital, 1094, 1105, 1116, 1175
tumors of. See Adrenal tumors
Adrenal crisis, 1154–1155
Adrenal hemorrhage, 1153
Adrenal insufficiency. See Adrenocortical insufficiency
Adrenal tumors
amenorrhea caused by, 1179
cancer, 1158, 1159, 1160, 1161, 1162,
1189, 1596r, 1612r
cortical, 1158
aldosterone-secreting, 438, 1164, 1165, 1166
androgon-secreting, 1162
cortisol-secreting, 1158, 1159, 1161
medullary. See Pheochromocytoma
in MEN, 1189
paraneoplastic syndromes associated with, 1196
Adrenal vein sampling, in adosteronism, 1165
Adrenalectomy/medical adrenalectomy
cortical crisis and, 1154
for adosteronism, 1165, 1166
for breast cancer, 740
in male, 746
for congenital adrenal hyperplasia, 1163
for Conn syndrome, 1166
for Cushing syndrome, 1160, 1161
Nelson syndrome after, 1160
Adrenergic drugs. See Alpha-adrenergic agonists; Alpha-adrenergic blocking drugs; Beta-
adrenergic agonists; Beta-adrenergic blocking drugs
Adrenocortical insufficiency, 1093, 1094, 1095
acute, 1154–1155
chronic, 1155–1158. See also Addison disease
congenital, 1155
corticosteroids causing, 1093, 1096, 1154
in HIV infection/AIDS, 1157, 1330

RAW_TEXT_END
hypercalcemia and, 1142, 1154, 1156
hyperkalemia and, 879, 1154, 1157
hypernatremia and, 871f, 872, 1154, 1156
perioperative corticosteroid replacement and, 54
Adrenocorticosteroids. See Corticosteroids
Adrenocorticotropic hormone (ACTH) deficiency of, 1093, 1094, 1095, 1156. See also Adrenocortical insufficiency
ectopic/hypersecretion of, 1158, 1159, 1160, 1161, 1172
in hypertension, 437
petrosal sinus levels of, in Cushing syndrome, 1139
pituitary adenoma secreting, 1158, 1189
plasma levels of in acute adrenal insufficiency, 1154
in Addison disease, 1156
in hypercortisolism/Cushing syndrome, 1159
reference values for, 1727r
Adrenoleukodystrophy, 1155–1156, 1156, 1157, 1157–1158
Adriamycin. See Doxorubicin
Adrucil. See Fluorouracil
Adson test, 1031
Adult respiratory distress syndrome. See Acute respiratory distress syndrome
Adult Still disease, 831
Adult T cell lymphoma/leukemia (ATL), 1383–1384. See also Human T cell lymphotropic/leukemia virus
Advance care planning/advance directives, 89
ADVANCE study, 356, 1204
Advil. See Ibuprofen
Adynamic (paralytic) ileus, 1053, 1204
Afer, 1064
Agranulocytosis. See Fluorouracil
Age-related maculopathy, 181
Age-related macular degeneration, 225
Age-Related Eye Disease Study (AREDS), 175
Age/aging, 1484–1485
Age/aging complications and, 50
breast cancer and, 1622
dementia and, 59–63, 1005–1010, 1008r
facial changes related to, 1720–1721
fever/FUO and, 1276
foreign body aspiration and, 238–239
hearing loss and (presbyacusis), 198, 206
hyper tension/hypertension management and, 435, 435, 436, 437, 458, 459
luteinizing hormone affected by, 1173
maternal, Down syndrome and, 1666
menopause and, 1666
postoperative delirium and, 53, 53t
postoperative pulmonary complications and, 50
prostate cancer and, 1630, 1631, 1632, 1633, 1635f, 1637t
PSA reference ranges and, 1631–1632
radiation-related carcinogenesis and, 1555
sleep changes and, 1075
testosterone deficiency/hypogonadism and, 1096, 1173, 1175
in women, 1185
vision impairment and, 72
Age-Related Eye Disease Study (AREDS), 181
Age-related macular degeneration, 180–181
Age-related maculopathy, 181
Agenerase. See Amprenavir
Agglutinins
aggregation in, 1385
Aggregation of platelets, 1708
Aggregation of white blood cells, 1114–1115
AIDS. See Human Immunodeficiency Virus
AIDS enteropathy, 1330
AIDS cholangiopathy, 1364, 1507
AIDS enteropathy, 1330
AIDS wasting syndrome, 1325
AIF. See Acute intermittent porphyria; Acute interstitial pneumonia
Air bronchogram in ARDS, 322
in bronchial obstruction, 243
Air travel compression stocking use during, 34
dysbarism/decompression sickness and, 1557, 1538
eustachian tube dysfunction/barotrauma and, 202
lower extremity edema and, 33, 34
medical safety/patient selection and, 1560–1561
during pregnancy, 786, 1560
retinal detachment and, 180
SARS transmission and, 1400, 1401
venous thromboembolism and, 34, 1560
AIRE gene, in type 1 diabetes, 1193
Aire, in diphtheria, 1433, 1434
Aire in patients, 86–87
Agnogenic myeloid metaplasia (primary myelofibrosis), 511r, 514–515
Agonist
in dementia, 39
intracranial tumors causing, 991
Agoraphobia, 1041
Agranulocytosis. See also Neutropenia
drug-induced, 510
clozapine causing, 1000, 1056, 1059
mirtazapine causing, 1068
thiourea therapy causing, 1114–1115
“A(H1N1)pdm09” (swine-origin) influenza, 23, 214, 1395, 1396, 1399–1400. See also Influenza
drug resistance and, 1396, 1399
prevention of, 1400. See also H1N1 influenza vaccine
AI. See Aromatase inhibitors
Aichi virus, gastrointestinal caused by, 1404–1405
Aid to Capacity Evaluation, evaluation of decision-making ability and, 73
AIDS. See Human Immunodeficiency Virus
AIDS cholangiopathy, 1364, 1507
AIDS enteropathy, 1330
AIDS wasting syndrome, 1325
AIP. See Acute intermittent porphyria; Acute interstitial pneumonia
Air bronchogram in ARDS, 322
in bronchial obstruction, 243
Air travel compression stocking use during, 34
dysbarism/decompression sickness and, 1557, 1538
eustachian tube dysfunction/barotrauma and, 202
lower extremity edema and, 33, 34
medical safety/patient selection and, 1560–1561
during pregnancy, 786, 1560
retinal detachment and, 180
SARS transmission and, 1400, 1401
venous thromboembolism and, 34, 1560
INX
Airway disorders, obstruction (Cont.): foreign body causing, 238–239, 308 in hypoparathyroidism, 1136, 1137 of lower airways, 242–243 occupational disorders and, 310–311 in recurrent respiratory papillomatosis, 234 during sleep (obstructive sleep apnea), 231, 318, 318–319 tracheostomy and cricothyrotomy for, 238 of upper airways, 242 respiratory failure caused by, 320 tridor and, 233 thermal injury, smoke inhalation and, 307, 1550 upper airway, 242

Airway management. See also Intubation burn injury and, 1550 for coma, 1014, 1562–1563 in hypoparathyroidism, 1137 tracheostomy and cricothyrotomy in, 238 Akathisia, 1004 antipsychotic drugs causing, 1060 SSRIs causing, 1067 AKIN criteria, in acute kidney injury, 901 Akinetic mutism (persistent vegetative state), 1016 Akineton, See Biperiden AL (primary) amyloidosis, 530–532, 920t, 930. See also Amyloidosis Al-Anon, 1079, 1082 Ala-Ala. See Teplizumab Alanine aminotransferase (ALT), 664, 664t. See also Aminotransferase levels in acute fatty liver of pregnancy, 795 in alcoholic liver disease, 681 in liver disease/jaundice, 644, 644t monitoring, in tuberculosis therapy, 4 in nonalcoholic fatty liver disease, 684, 685 olanzapine affecting, 1057 reference/normal values for, 664t, 1727t in viral hepatitis, 666, 666f, 668f, 671f, 675 Alarm response, 1041 Albendazole for ascasiasis, 1517 for clonorchiasis/opisthorchiasis, 1513 for cutaneous larva migrans, 1523 for cystercerosis, 1515 for enterobiasis/pinworms, 1520 for filariaisis, 1525–1526 for giardiasis, 1509 for gnathostomiasis, 1523 for hookworm disease, 1518 for hydatid disease, 1516 for microsporidiosis, 1508 for strongyloidiasis, 1519 for trichinosis, 1522 for trichuriasis/whipworm, 1518 Albinism, 155 Albinism-associated storage pool disease, 548 Albright hereditary osteodystrophy, 1137

INDEX

Albumin ascitic fluid, 588. See also Serum-ascites albumin gradient in cirrhosis, 686, 688, 692t serum levels of albumin gap and, 890 calcium levels and, 882, 883, 1136, 1646 in liver disease/jaundice, 644t in myeloma staging, 529 in nephrotic syndrome, 927 postoperative pulmonary complications and, 51 in protein-losing enteropathy, 631, 632 reference/normal values for, 664t, 1727t urinary. See Albuminuria Albuminuria, 899. See also Proteinuria in diabetes/diabetic nephropathy, 931, 1224 glycemic control and, 931, 1201, 1224 Albuterol for asthma, 254t, 255 with ipratropium, 254t for cystic fibrosis, 268 for hyperkalemia, 881t Alclometasone, 95 Aldesleukin. See Interleukin-2 Aldehyde dehydrogenase deficiency, 1042 Aldolase, in polymyositis/dermatomyositis, 1160

Aldomet. See Methyldopa

INDEX

Aldosterone. See also Aldosteronism; Hypoaldosteronism
adrenal adenoma/hyperplasia
secretion, 438, 1164, 1165, 1166
drugs blocking receptors for. See also Spironolactone
for heart failure, 402
for hypertension, 437, 438, 442r, 445r, 449–453
for myocardial infarction, 371
in hypertension, 437, 438, 440, 453, 1164, 1165
resistant disease and, 438, 453, 460, 1164, 1165
potassium balance and, 402, 878, 879, 1164
in renal tubular acidosis, 892, 892r, 933
serum/urine levels of
in primary aldosteronism, 438, 1165
reference values for, 1727r
in steroidogenic enzyme defects, 1166
Aldosterone:renin ratio, 437, 1164, 1165
Aldosteronism (hyperaldosteronism), 437–438, 1164–1166
glucocorticoid-remediable, 437, 878r, 1164, 1166
hypertension and, 437, 437–438, 440, 453, 1164, 1165
hypokalemia and, 878, 1164
primary, 437–438, 1164–1166
sodium-unresponsive metabolic alkalosis and, 895, 1164
Alfercept. See also Anti-TNF agents
for psoriasis, 108
Alemtuzumab, 1653r
for aplastic anemia, 509

with osmolar gap, 877, 1569
in poisoning/drug overdose, 891, 1569
with methanol or ethylene glycol, 877, 891, 1589–1590
with salicylates, 891, 1588–1589
Antidepressants
for gram-negative infections, 1299r, 1299–1300r, 1444 for gram-positive infections, 1299r, 1300r
in H pylori eradication therapy, 609, 613–615, 614r, 615 for hepatic encephalopathy, 690 hypersensitivity tests/desensitization and, 1305–1307 in immunocompromised host, 1281–1282, 1648 for impetigo, 97t, 123, 1303r infection in cancer patient and, 1648 intravenous administration of, 1305 for irreversible bowel syndrome, 635 for liver abscess, 701 for malaria, 1497 for meningitis, 1286r, 1288, 1424–1425 partial treatment and, 1286–1287 for mycoplasma infection, 1301r in neutropenic patient, 36, 510, 1281, 1281–1282, 1648 ophthalmic, 168r oral contraceptive failure and, 127 periorbital pulmonary complications and, 51 for surgical site infections, 55–56 for pharyngitis, 228, 229, 1303r, 1420 for PID, 763, 1304r platelet function affected by, 549r for pneumonia anaerobic, 278–279, 1302r, 1303r, 1455 in community-acquired disease, 270, 271, 272–274, 273r, 274, 1302r nosocomial, 277, 277r, 1302r pneumococcal, 1423 principles of use of, 1298–1305, 1299–1301r, 1302r, 1303–1304r prophylactic. See Antimicrobial chemoprophylaxis resistance to. See Drug resistance for rickettsial infections, 1301r routes of administration for, 1305 for shock, 489 for skin and soft tissue infections, 1420–1421, 1421r for sprochetal infections, 1300r for spontaneous bacterial peritonitis, 589, 590, 689 for syphilis, 1467, 1468r thrombocytopenia caused by, 547r topical for acne, 97t, 127 for impetigo, 97t, 123 tubulointerstitial nephritis caused by, 932r for urinary tract infections, 940t, 1303r Antibodies. See also Immunoglobulins infections associated with defects in, 1279 Antibody-mediated (cytotoxic/type II) hypersensitivity, 866 Anticancer drugs. See Chemotherapy Anticardiolipin antibodies in antiphospholipid antibody syndrome, 799, 834, 836 pregnancy loss and, 789 in SLE, 834, 834r Anti-CCP antibodies, in rheumatoid arthritis, 827 Anti-CD3 antibodies, in new-onset type 1 diabetes, 1202 Anticentromere antibody, 833r in CREST syndrome/scleroderma, 833r, 839 Anticholinergic agents for allergic disorders/rhinitis, 219 antidepressant drug interactions and, 1071r for asthma, long-acting, 252, 252r short-acting, 254r, 255 breastfeeding and, 782r for COPD, 262 for irritable bowel syndrome, 634–635 for nausea and vomiting, 86, 569 overdose/toxicity of, 999, 1566r, 1575, 1583 ophthalmic effects and, 195r, 196r for parkinsonism, 998, 999, 999r Anticholinergic delirium, 1568, 1575, 1583 Anticholinergic syndrome/effects, 1568, 1575, 1583 antidepressants causing, 1068–1069, 1070r, 1575, 1591 antipsychotic drugs causing, 1055, 1057r, 1059 hallucinogens causing, 1583 Anticholinergic-type mushroom poisoning, 1575, 1583 Anticholinesterases/acyetylcholinesterase inhibitors for Alzheimer disease/dementia, 61, 1008–1009 for myasthenia gravis, 1032–1033 overdose/toxicity/poisoning with, 1566r, 1587 for parkinsonism, 1000 Anticipatory anxiety, in panic disorders, 1041 Anticoagulants, lupus. See Lupus Anticoagulant Anticoagulation therapy, 554–555, 556–562, 557r, 558r, 559r, 560r, 561r, 562r for acute arterial occlusion of limb, 468 for acute coronary syndromes, 361–363, 362r for antiphospholipid antibody syndrome, 799, 836 in pregnancy, 799, 836 in SLE, 834 for atrial fibrillation, 385r, 386–387, 388 in hyperthyroidism, 1118 in mitral stenosis, 338 for atrial flutter, 389 bleeding and, 302–303 after cardiac valve replacement, 343, 349 endocarditis and, 1439 pregnancy and, 349 drug interactions and, 560r antidepressants, 1071r for DVT/PE (venous thromboembolic disease) drug selection and, 556–562, 559r, 560r, 561r, 562r duration of, 301–302, 558–560, 562r patient selection and, 560r prevention and, 301, 555–556, 555r, 556r, 557r, 558r treatment and, 301–303, 556–562, 559r, 560r, 561r, 562r in endocarditis, 1439 epistaxis and, 220 for heart failure, 405 hematuria and, 938 heparin-induced thrombocytopenia and, 544–545, 544r, 554 for hepatic vein obstruction (Budd-Chiari syndrome), 698 for intracranial venous thrombosis, 988 investigational agents in, 558 for myocardial infarction, 362r, 367, 371, 376 after thrombolytic therapy, 369–370 for nephrotic syndrome/nephrotic spectrum disorders, 928 overdose/toxicity and, 1573 peptic ulcer disease and, 613 perioperative management of, 52, 53r for pulmonary hypertension, 305, 424, 425f for septic superficial thrombophlebitis, 480 for stroke, 982 thrombocytopenia caused by, 547r for transient ischemic attacks, 978–979 Anticoagulants, in autoimmune diseases, 208 Anticonvulsant therapy, 972, 973r breastfeeding and, 782r corticosteroid interactions and, 1190 discontinuing, 972 drug selection and, 972, 973r for glossopharyngeal neuralgia, 968 for migraine prophylaxis, 964r monitoring serum levels during, 972 for myoclonus, 1004 overdose/toxicity and, 972, 1573–1574 for postherpetic neuralgia, 968 during pregnancy, 803, 972 for PTSD, 1040 for status epilepticus, 974 thyroid testing affected by, 1108 for trigeminal neuralgia, 967 vitamin D affected by, 1149 Anti-CV2/CRMP5 antibody, in autoimmune paraneoplastic disorders, 995 Anti-D, for immune thrombocytopenia, 541, 541f, 542 Anti-D antibodies, transfusion producing, 534 Antidepressants, 1065–1069, 1066f, 1069r, 1070r, 1071r. See also specific type and agent with antipsychotic agents, 1058, 1065–1066, 1069 for anxiety, 1042, 1043–1044 aripiprazole with, 1058, 1069 atypical, 1067–1068
INDEX

Antidepressants (Cont.):
- breastfeeding and, 782r
- buspirone as augmenting agent for, 1065, 1069
- combination therapy and, 1069 in dementia, 61, 1009
- dispensing, 1065, 1067
dose tapering and, 1069
drug interactions of, 1071r
- for dyspepsia, 566
- in elderly, 63, 71
- for irritable bowel syndrome, 635
- for migraine prophylaxis, 964
- for neuropathic pain/painful diabetic neuronopathy, 84, 84t, 1021, 1049, 1225
- for OCD, 1044, 1067, 1068
- overdose/toxicity of, 1070r
- for panic attacks, 1044
- for phobic disorder, 1044 during pregnancy, 1067–1068
- for psychotic depression, 1058, 1065–1066, 1068
- for PTSD, 1040
- selection of, 1065
- sexual dysfunction caused by, 1051, 1067, 1069
- SSRIs, 1067–1068, 1070t. See also Serotonin-selective reuptake inhibitors
- switching agents and, 1069
- thyroid medication/lithothyrine as augmenting agent for, 1065, 1069
- tricyclic, 1068–1069, 1070t. See also Tricyclic antidepressants
Antidepressant agents, 97–98t, 1049–1053, 1049–1050, 1052–1053, 1054–1055t
- abacavir interactions and, 1071r
- overdose/toxicity of, 1566r
- during pregnancy, 801, 1230
- in prevention/delay of diabetes, 1201, 1201–1202, 1202
- Antidiabetic agents, 1205–1213, 1206–
- in glucose metabolism, 1207
- for irritable bowel syndrome, 635
- for microscopic colitis, 650
- for short bowel, 626
- for traveler’s diarrhea, 1298
- for ulcerative colitis, 647
- Antidiuretic hormone (ADH). See also Vasopressin
- antipsychotic drugs affecting, 1059 in diabetes insipidus/hypernatremia, 876
- in hyponatremia, 871, 871f, 872, 873
- inappropriate secretion of (SIADH). See Syndrome of inappropriate ADH secretion volume overload and, 877

hypertension/hypertension control and, 10–11, 433, 434, 439, 441–442, 442–444, 442r, 443f, 444, 457
in women, 1706
in hyperthyroidism, 1112, 1114, 1118–1119
in hypothyroidism, 1108
immobility/bed rest and, 65
lipid disorders and, 8–10
in Lyme disease, 419, 1479, 1481–1482, 1482r
in pheochromocytoma/paraganglioma, 1167, 1168t, 1169, 1170
pregnancy and, 429–431, 802–803
prooperative evaluation/perioperative management and, 46–50, 47r, 48f, 48r
prevention of, 5–11, 7r
abdominal aortic aneurysm
screening in, 6, 7r, 473
chemoprevention/aspirin use and, 7r, 11, 1253
in women, 1707
cholesterol screening and, 7r, 8–10, 1248–1252, 1249–1250r, 1251r
in women, 7r, 1248, 1251, 1706
exercise/activity and, 7r, 12–13
hypertension prevention/management and, 7r, 10–11, 439, 441–442, 442–444, 442r, 443f, 444, 457
in women, 1706
lipid disorder prevention/management and, 7r, 8–10, 1246–1247, 1252–1255, 1255r. See also Lipid-lowering therapy
smoking/smoking cessation and, 6–8, 7r, 9–10, 10r
in women, 1249r, 1251, 1706–1707
radiation causing, 1554
syphilis and, 1304r, 1464, 1471, 1471f
in Turner syndrome, 1186, 1187, 1187r
Cardiovascular system
abnormal development of,
hypertension and, 435–436
thiamine deficiency affecting, 1264
Cardioversion
electrical
for atrial fibrillation, 385, 386, 387
in hyperthyroidism, 1118
infarct-related, 372
rate control compared with, 387–388
for atrial flutter, 389
in hypothermia, 1454
for supraventricular tachycardia, 382
for ventricular arrhythmias/tachycardia/fibrillation, 391
infarct-related, 373
pharmacologic
for atrial fibrillation, 387–388
for atrial flutter, 389
transesophageal echocardiography-guided, for atrial fibrillation, 386
Cardioverter defibrillator, implantable.
See Implantable cardioverter defibrillator
Carditis, rheumatic, 417, 417–418, 418
Cardizem. See Diltiazem
Carisoprodol, overdose/toxicity of, 1682
Caregiver issues
in care of elderly, 58–59
terminal illness/dying patient and, 88, 88r
Carey-Coombs murmur, in rheumatic carditis, 417
Carisoprodol, overdose/toxicity of, 1579–1580
Carmel, 98r
Carney complex/syndrome, 426, 1190
acromegaly and, 1100
Cushing syndrome and, 1158
thyroid cancer and, 1123
β-Carotene/carotenoids
in chemoprevention, 11
excess intake of, 1267
Carotid angioplasty, 470
Carotid artery dissection
headache and, 41, 966
retinal artery occlusion and, 183
Carotid artery occlusive disease (carotid stenosis/insufficiency), 469–470
headache associated with, 966
recurrent, 470
retinal artery occlusion and, 183, 469
stroke/transient ischemic attacks caused by, 469–470, 977, 978, 980r, 981
postoperative stroke and, 54
transient monocular blindness and, 184, 469, 981
Carotid bruits, 469
postoperative stroke and, 54
Carotid endarterectomy/thromboendarterectomy, 470
prophylactic, 469
preoperative, 54
transient monocular blindness and, 184
stroke as complication of, 469–470
for transient ischemic attacks and stroke, 469, 470, 978
Carotid insufficiency. See Carotid artery occlusive disease
Carotid pulse
in cardiomyopathy, 414
in heart failure, 399
CMDT 2013

immune reconstitution and, 1333
MAC infections and, 1337, 1458, 1459
opportunistic infection/course of
disease and, 1322–1323, 1323f, 1324, 1334r, 1336, 1339, 1349
percentage of, 1319, 1324, 1324r
Pneumocystis pneumonia and,

INDEX

Listeria monocytogenes (listeriosis) 574

Liver

Liver (hepatic) failure 672–674, 673

Liver flukes, 1527–1528

Liver-kidney transplantation 691

Liver-kidney microsomes, antibody to, in autoimmune hepatitis 553–554

Liver spots (solar lentigines) 101, 155, 1583

Liver abscesses of amoebic 1508

antiphospholipid antibody syndrome and 582, 585

in polyarteritis nodosa 578

Liver spots (solar lentigines) 101, 155, 1583

Liver abcesses of amoebic 1508

pyogenic 701, 701

anesthesia/surgery affecting function of 56

biopsy of in alcoholic liver disease 681

in cirrhosis 55

in hemochromatosis 562

in hepatic vein obstruction (Budd-Chiari syndrome) 698

in hepatocellular carcinoma 608

in nonalcoholic fatty liver disease 553

in noncirrhotic portal hypertension 570

in primary sclerosing cholangitis 570

cancer of in cirrhosis and 688, 688, 689, 1608

hemochromatosis and 561

hepatitis and 653, 656, 656

hepatitis B vaccine in prevention of 1583

incidence/mortality/risk of 1603

paraneoplastic syndromes associated with 1536

pyogenic abcess and 701

carcinoid metastases involving 1623

cavernous hemangiomata of, 701

disorders of 665, 703

See also Specific disorder and under Hepatic

cancer liver failure 672, 673

alcoholic 680, 682, 1083, 1083

ascites in spontaneous bacterial peritonitis and 583, 587

biliary cirrhosis 692, 694

bleeding associated with 553

cholelithiasis/gallstones and 704

hemodialysis for 1073

monitoring levels of 1073

drug overdose/toxicity of 1073–1074

hemochromatosis, 1073

monitoring levels of 1073

hypothyroidism and 1072

monitoring levels of overdose/toxicity of 1073

passive congestion of 581

pregnancy/breastfeeding and 782

pregnancy/breastfeeding and 1073

for Alzheimer's disease 457

for aggressive/violent patient 1434

meningitis caused by 1302

incidence/mortality/risk of 1603

hepatitis B vaccine in prevention of 1603

in primary sclerosing cholangitis 676, 678, 679, 1603

in nonalcoholic fatty liver disease 685

in hepatocellular carcinoma 1604

for acute liver failure 674

adenovirus infection and 1402

alcoholic liver disease and 682

for autoimmune hepatitis 680

for biliary cirrhosis 694

biliary stricture and 1603

for cholangiocarcinoma 1607

for cirrhosis 685, 686, 689, 693

CMV infection and 1368

esophageal varices and 604

for hepatic coagulopathy 556

for hepatic vein obstruction (Budd-Chiari syndrome) 692

for hepatocellular carcinoma 1605

for hepatopulmonary syndrome/portopulmonary hypertension 693

for hepatorenal syndrome 689

for mushroom poisoning 672, 1585

for nonalcoholic fatty liver disease 685

for Wilson disease 659

Liver biochemical tests. See also specific test evaluation of 664

Liver cell adenoma. See Hepatocellular adenoma

Liver (hepatic) failure 672, 674

acetylaminophen causing 76

acute 672, 674

fatty liver of pregnancy and 673

anemia in 493

in cirrhosis 689

drugs/toxins causing 653

for herpes simplex 1434–1435

for HIV infection/AIDS 1329

in mushroom poisoning 672, 674

for nonalcoholic fatty liver disease, 685

nefazodone causing 1068

Liver flukes 1512

Chinese 1512

sheep 1512

Liver-kidney microsomes, antibody to, in autoimmune hepatitis 679

Liver-kidney transplantation 691

Liver spots (solar lentigines) 101

Liver stiffness, in hepatic fibrosis 685

Livial. See Telbivudine

Livostin. See Telbivudine

LKB1/STK11 mutation, pancreatic/peripancreatic carcinoma and 1608

LMWH (low-molecular-weight heparin). See Heparin

Loa loa (loiasis) 1527–1528

Load and shift test 1629

Lobectomy pulmonary, for lung cancer 1509

See also Lung resection thyroid, for thyroid carcinoma 1172

Lobular carcinoma in situ 731

Local anesthetics, for eye disorders, precautions for use of 192

for neuropathic pain/diabetic
neuropathy, 84–85, 84t, 1021,
1225
for restless legs syndrome, 1004
for seizures, 973t
Pregnancy, 781–808
acne treatment and, 127
adverse ophthalmic effects of drugs
used in, 196t
air travel during, 786
alcohol use during, 783, 1081
amenorrhea (primary/secondary)
carried by, 781, 786, 1180,
1181
anemia during, 784, 798–799
antidepressant use during, 1067–1068
antiphospholipid antibody syndrome
during, 799–800, 834, 836
antipsychotic drug use during, 1060
appendicitis during, 630, 807
asthma during, 803
bleeding during
eptic pregnancy and, 790
in gestational tophloblastic disease,
791
third-trimester, 797
breast cancer and, 730, 743, 745,
807–808
breast cancer risk and, 722, 723t, 743,
1708
cardiac disease and, 429–431, 802–803
cardiomyopathy and
dilated (peripartum
cardiomyopathy), 429–430
hypertrophic constrictive, 415
Chlamydia trachomatis infection and,
784, 806, 1462
choledocholithiasis during, 807
cholelithiasis/cholecystitis during,
703, 704, 807
cholesterol of, 663t, 807
choioaomionitis and, 798
in chronic kidney disease, 914
CMV infection during, 1363–1364,
1364, 1364–1365, 1365
complications of
cardiovascular, 429–431, 802–803
first and second trimesters,
787–792
infectious conditions, 803–806
medical conditions, 798–803
periartum, 797–798
during second and third trimesters,
792–797, 793t
surgical, 807–808
coxsackievirus infection during,
neonatal myocarditis and,
1406
dengue and, 1387
depression durante, 1067–1068
depression after (postpartum
depression), 1063
diabetes insipidus and, 1098, 1099
diabetes mellitus and, 784, 800–801,
801t, 1230
continuous glucose monitoring
systems and, 1200
diagnosis/differential diagnosis of, 781
drug/medication use/avoidance during,
782t, 783. See also specific
agent
ECT during, 1071
ectopic, 790–791
elective abortion and, 776
hCG levels in, 781, 790
IUDs and, 774
minipill use and, 773
PID and, 763
ruptured, appendicitis differentiated
trom, 631, 790
electrical burns during, 1553
endocarditis prophylaxis and, 431, 803
erythrovirus (parvovirus) infection in,
1402, 1403
fatty liver of, 673, 795
folic acid deficiency/supplementation
during, 499, 783, 785, 799
gallbladder disease/surgery during,
703, 704, 807
genital warts/wart removal and, 140,
753
glucosuria and, 1198
gonorrea and, 784, 806
group B streptococcal infection and,
784–785, 804
growth hormone replacement during,
1097
headache during, preeclampsia and, 41,
793
heart disease and, 429–431, 802–803
hepatitis B and, 667, 783, 806
vaccination/vaccination
recommendations and, 669,
786, 806, 1309t
hepatitis C and, 670, 671, 806
testing for, 783
hepatitis E and, 672
herpes infection during, 806, 1351,
1355, 1366
HIV infection/AIDS in, 783, 784,
805–806, 1321, 1336
hypercortisolism and, 1160
hyperparathyroidism during, 1139
hypertension and, 437, 438, 461t,
793–795, 793t, 802. See also
Preeclampsia-eclampsia
hypothyroidism/Glaves disease
during, 800, 1111–1112,
1113, 1117, 1121
methimazole for, 800, 1117
propylthiouracil for, 800, 1106,
1355, 1366
thyrotoxicosis and, 1160
thyroidectomy for, 1116, 1117
thyrotoxicosis of, reset osmostat and, 873
hypothyroidism/hypothyroidism
treatment during, 800, 1106,
1108, 1109
immune thrombocytopenia associated
with, 542
immunizations during, 786–787,
1307–1314, 1309r
influenza/H1N1 influenza vaccination
and, 3, 787, 1307, 1309r,
1395, 1396, 1399, 1400
iodine deficiency and, 1123, 1134

Zeta-associated protein (ZAP-70), in chronic lymphocytic leukemia, 522
Zetia. See Ezetimibe
Zevalin. See Ibritumomab tiuxetan
Ziac. See Bisoprolol, with hydrochlorothiazide
Ziagen. See Abacavir
Zidovudine (AZT), 1341r, 1343, 1347, 1348f. See also Antiretroviral therapy/HAAART
with lamivudine, 1343, 1347, 1348f postexposure/after needle stick, 1335 with lamivudine and abacavir, 1344, 1348f myopathy caused by, 1036, 1328 for prevention of HIV transmission to fetus/newborn, 805, 1336 postexposure/after needle stick, 1335–1336 resistance to, 1349
ZIFT. See Zygotte intrafallopian transfer
Zileuton, for asthma, 249, 252t, 253
Zinacef. See Cefuroxime
Zinc
parenteral nutritional support and, 1272, 1274r toxicity of, 1578r for viral rhinosinusitis (common cold), 23, 214 for Wilson disease, 697
Zinc-finger protein-9 gene, in myotonic dystrophy, 1034, 1035r
Zinc transporter 8 antibodies, in type 1 diabetes, 1193, 1193r
ZincCard. See Dextranoxane
Zioptan. See Tafluprost
Ziprasidone, 1055, 1056r, 1057–1058, 1057t, 1060r
overdose/toxicity of, 1057–1058, 1057t, 1059, 1060r, 1574
Zirgan. See Ganciclovir
Zithromax. See Azithromycin
ZnT8 antibodies, in type 1 diabetes, 1193, 1193r
Zocor. See Simvastatin
Zoladex. See Goserelin
Zoledronate/zoledronic acid, 1146, 1147.
See also Bisphosphonates in breast cancer management, 738, 739
for chemotherapy-induced toxicity/
bone pain, 1659
for hypercalcemia/
hyperparathyroidism, 1143, 1647
for osteoporosis prevention/
management, 1146, 1147
corticosteroid use and, 1191
for Paget disease of bone, 1153
for thyroid cancer bone metastases, 1130
Zollinger-Ellison syndrome (gastrinoma), 619–620, 1172, 1189
carcinoid tumors and, 1619
GERD and, 597, 619
in MEN, 619, 620, 1172, 1189
peptic ulcer disease and, 617, 619–620, 1172, 1189
Zolmitriptan
for cluster headache, 965
for migraine headache, 963–964
Zolof. See Sertraline
Zolpidem, 1042r, 1076
overdose/toxicity of, 1579–1580
Zometa. See Zoledronate/zoledronic acid
Zona-free hamster egg penetration tests, in infertility workup, 768
Zonalon. See Doxepin
Zonisamide, 972, 973r
for obesity, 1261
overdose/toxicity of, 973r, 1573
Zostavax. See Herpes zoster vaccine; Varicella vaccine
Zoster. See Herpes zoster
Zoster ophthalmicus, 120, 173, 1331, 1358
Zoster sine herpete, 1359
Zoster vaccine. See Herpes zoster vaccine
Zostrix. See Capsaicin
Zosyn. See Piperacillin-tazobactam
Zovirax. See Acyclovir
Zygomyces (mucormycosis), 1538, 1542
rhinocerebral, 217
Zygote intrafallopian transfer (ZIFT), 769
Zymar. See Gatifloxacin
Zyprexa. See Olanzapine
Zytiga. See Abiraterone
